Abstract

We investigate by means of Monte Carlo simulation and finite-size scaling analysis the critical properties of the three-dimensional O(5) non-linear $\sigma$ model and of the antiferromagnetic RP$^2$ model, both of them regularized on a lattice. High accuracy estimates are obtained for the critical exponents, universal dimensionless quantities and critical couplings. It is concluded that both models belong to the same universality class, provided that rather non-standard identifications are made for the momentum-space propagator of the RP$^2$ model. We have also investigated the phase diagram of the RP$^2$ model extended by a second-neighbor interaction. A rich phase diagram is found, where most of the phase transitions are of the first order.

1. Introduction

Universality is sometimes expressed in a somehow defectively simple way: some critical properties (the universal ones) of a system are given by space dimensionality and the local properties (i.e., near the identity element) of the coset space $G/H$, where $G$ is the symmetry group of the high-temperature phase and $H$ is the remaining symmetry group of the broken phase (low temperature). As we shall discuss, the subtle point making the above statement not straightforward to use, is that $G$ needs not to be the symmetry group of the microscopic Hamiltonian, but that of the coarse-grained fixed-point action.

On the spirit of the above statement, some time ago [1] a seemingly complete classification was obtained of the universality classes of three-dimensional
systems where $G = O(3)$. In this picture, a phase transition of a vector model, with $O(3)$ global symmetry and with an $O(2)$ low-temperature phase symmetry, in three dimensions must belong to the $O(3)/O(2)$ scheme of symmetry breaking (classical Heisenberg model). In addition, if $H = O(1) = Z_2$ is the remaining symmetry, the corresponding scheme should be $O(4)/O(3)$ which is locally isomorphic to $O(3)/O(1)$.1 This classification has been challenged by the chiral models [2]. However, the situation is still hotly debated; some authors believe that the chiral transitions are weakly first-order [3], while others claim [4] that the chiral universality class exists, implying the relevance of the global properties of $G/H$.

In this Letter, we shall consider the three-dimensional antiferromagnetic (AFM) $\mathbb{RP}^2$ model [5–8], a model displaying a second-order phase transition and escaping from the previously expressed paradigm. It is worth recalling [9,10] that one of the phase transitions found in models for colossal magnetoresistance oxides [11] belongs to the universality class of the AFM $\mathbb{RP}^2$ model. The microscopic Hamiltonian of this model has a global $O(3)$ symmetry group, while the low-temperature phase symmetry has, at least, a remaining $O(2)$ symmetry [9]. We will show here that the model belongs to the universality class of the three-dimensional $O(5)$ non-linear $\sigma$ model. Some ground for this arises from a hand-waving argument, suggested to us by one of the referees of Ref. [9] (see below).

The universality class of the three-dimensional $O(5)$ non-linear $\sigma$ model has received less attention than $O(N)$ models with $N = 0, 1, 2, 3$ and 4. In spite of that, it has been recently argued that $O(5)$ could be relevant for the high-temperature superconducting cuprates [12]. Nevertheless, perturbative field-theoretic methods have been used to estimate the critical exponents [13–16]. From the numerical side, only a rather unconvincing Monte Carlo simulation [17] was available until very recently. Fortunately, there has been a recent, much more careful study [18]. Yet, the scope of Ref. [18] was to determine whether an interaction explicitly degrading the $O(5)$ symmetry to an $O(3) \oplus O(2)$ group was relevant in the renormalization-group sense. To that end, those authors concentrated in producing extremely accurate data on small lattices.

Our purpose is to study in greater detail the critical properties of the three-dimensional $O(5)$ non-linear $\sigma$ model, and of the AFM $\mathbb{RP}^2$ model. We improve over previous studies of both models, obtaining more accurate estimates for critical exponents, universal dimensionless quantities and non-universal critical couplings. As symmetries play such a prominent role, we will also explore the possibilities of changing those of the low-temperature phase by adding a second-neighbors coupling to the Hamiltonian of the AFM $\mathbb{RP}^2$ model.

2. The models

We are considering a system of $N$-component normalized spins $\{\vec{v}_i\}$ placed in a three-dimensional simple cubic lattice of size $L$ with periodic boundary conditions. The actions of our lattice systems are

$$S^{O(N)} = -\beta \sum_{\langle i,j \rangle} (\vec{v}_i \cdot \vec{v}_j),$$

$$S^{\mathbb{RP}^{N-1}} = -\beta \sum_{\langle i,j \rangle} (\vec{v}_i \cdot \vec{v}_j)^2,$$

where the sums are extended to all pairs of nearest neighbors. Our sign convention is fixed by the partition function:

$$Z = \int \prod_i d\vec{v}_i \ e^{-S},$$

$d\vec{v}$ being the rotationally invariant measure over the $N$-dimensional unit sphere.

To construct observables, in addition to the vector field $\vec{v}_i$, we consider the (traceless) tensorial field

$$\tau_i^{\alpha\beta} = v_i^\alpha v_i^\beta - \frac{1}{N} \delta^{\alpha\beta}, \quad \alpha, \beta = 1, \ldots, N.$$  

The interesting quantities related with the order parameters can be constructed in terms of the Fourier transforms of the fields ($f_i = \vec{v}_i, \tau_i$)

$$\hat{f}(\vec{p}) = \frac{1}{L^3} \sum_i e^{-i\vec{p} \cdot \vec{r}_i} f_i.$$  

For $\mathbb{RP}^{N-1}$ models, the local gauge invariance $\vec{v}_i \rightarrow -\vec{v}_i$ implies that the relevant observables are

---

1 This statement assumes that the global properties of the coset $G/H$ are irrelevant, only the local properties matter.
constructed in terms of the tensor field. However, for
O(N) we have found very interesting to consider as
well quantities related with the tensor field.

We construct the scalars (under global O(N) trans-
formations and spatial translations)
\[ S_V(p) = \hat{v}(p) \cdot \hat{v}^*(p), \]
\[ S_T(p) = \text{tr} \hat{\tau}(p) \hat{\tau}^*(p), \]
which, in addition to the action, are the only quantities
measured during the simulation. Their mean values
yield the propagators:
\[ G_{T,V}(p) = L^3 \langle S_{T,V}(p) \rangle. \]

In the thermodynamic limit and at the critical point,
the propagator is expected to have poles at \( p_0^f = (0,0,0) \) and, for the antiferromagnetic model, at \( p_0^s = (\pi,\pi,\pi)^2 \):
\[ G(p_0 + \delta p) \approx \frac{Z^{1 - \eta}}{Z^{1 - \eta}}. \]

where \( \xi \parallel \delta p \parallel \ll 1 \), and the exponents \( \eta^f \) and \( \eta^s \) corre-
spond to independent wave function renormalization
at each pole. Note that close to the critical point \( \xi^f \) and
\( \xi^s \) are expected to remain proportional to each other
(this will be explicitly checked numerically).

The (non-connected) susceptibilities are simply:
\[ \chi = G(p_0). \]

In a finite lattice an extremely useful definition of
the correlation length can be obtained from the (dis-
crete) derivative of \( G(p) \). Using \( \delta p = (2\pi/L,0,0) \) one obtains [19,20]
\[ \xi = \left( \frac{G(p_0) / G(p_0 + \delta p) - 1}{4 \sin^2(\pi/L)} \right)^{1/2}. \]

We also compute the cumulants
\[ U_4 = \frac{\langle S^2 \rangle}{\langle S \rangle^2}. \]

Finally, the energy per link is
\[ E = \langle S / (3\beta L^3) \rangle. \]

We have computed \( \beta \)-derivatives of observables
through their connected correlation with the action.
Furthermore, we have extrapolated mean-values from
the simulation coupling, to a neighboring value of \( \beta \)
using the standard reweighting techniques, that cover
all the relevant part of the critical region [20].

The relationship between the O(5) model and the
RP^2 model arises from the Landau–Wilson–Fisher
Hamiltonian for the RP^2 system [9]. Indeed, at the
mean field level [6,9], the ferromagnetic quantities are
simple functions of the staggered ones. This suggests
to construct the Landau–Wilson–Fisher Hamiltonian
from the staggered magnetization, which is a traceless,
real, symmetric \( 3 \times 3 \) matrix:
\[ M^a_{\alpha\beta} = \sum_i (-1)^{y_i + z_i} \epsilon^{a\alpha\beta}_i. \]

Note that \( M_4 \) has 5 independent quantities. It is therefore
simple matter to obtain a five-components real
vector \( \vec{v} \) such that \( \vec{v}^2 = \text{tr} M^2_4 \). The less trivial part regards
the fourth-order interaction terms. In principle, the O(3)
symmetry of the microscopic Hamiltonian
would allow for a \( \text{tr} M^4 \) and a \( \text{tr} M^2_4 \) one. Sur-
prisingly enough, both terms are proportional to \( \langle \vec{v}^2 \rangle^2 \).
Thus, assuming that sixth-order terms are irrelevant,
the Landau–Wilson–Fisher Hamiltonian is expected to
have a O(5) symmetry group and both models belong
to the same universality class. This does not only im-
plies that both models have the same critical exponents
but also that the \( L \to \infty \) limit of \( U_4^{O(5)} \) and of \( U_4^{S,RP^2} \)
(evaluated at their respective critical couplings) coin-
ide.

3. Numerical methods

In the O(5) model we have studied lattice sizes
\( L = 6,8,12,16,24,32,48,64,96 \) and \( L = 128 \), at
\( \beta = 1.1812 \). We have combined a Wolff’s single
cluster update with Metropolis. Our elementary
Monte Carlo step (EMCS) consists of \((10L + 1) \) Wolff’s
cluster updates and then a full-lattice Metropolis
sweep. We take measurements after every EMCS. Since
the average size of clusters grows as \( L^{2-s} \approx L^2 \), 80%
of simulation time we are tracing clusters for all \( L \),
while Metropolis accounts for 10% of time and mea-
surements for the remaining 10%. The total simulation
time has been equivalent to 600 days of Pentium IV

\footnote{In the remaining part of this section, if a subindex V or T does not explicitly appears, it will imply that the equation is valid both for vector or tensor quantities. The same convention will apply for superscript (f) (ferromagnetic) and (s) (staggered). Staggered quantities are useful only for antiferromagnetic models.}
at 3.2 GHz. The number of EMCS ranges from $10^8$ for $L = 6$ to $1.4 \times 10^6$ at $L = 128$. The integrated autocorrelation times for the susceptibility and for the energy are smaller than 1 EMCS for all the simulated lattice sizes.

Since we are interested in high accuracy estimates, we have used double precision arithmetics. One also needs to worry about the pseudo-random number generator. We have therefore implemented a Schwin-
ger–Dyson test. It turned out that the 32-bits Parisi–Rapuano pseudo-random number generator [21] produces biased results. Either the Parisi–Rapuano plus congruential generator [22] or the 64 bits Parisi–Rapuano generator cured this bias. The 64 bits Parisi–Rapuano generator is faster and it has been our final choice.

For the antiferromagnetic RP$^2$ model, no efficient cluster method is available. We have simulated in lattice sizes from $L = 8, 12, 16, 24, 32, 48$ and $L = 64$ at $\beta = -2.41$. We used a multi-hit Metropolis sequential algorithm. Making a new spin proposal completely independent from the previous spin value, we achieve an acceptance of about 30%. We have used 2 hits what ensures a 50% acceptance. The observables have been measured every two Metropolis full-lattice sweep (our algorithm. Making a new spin proposal completely independent from the previous spin value, we achieve an acceptance of about 30%. We have used 2 hits what ensures a 50% acceptance. The observables have been measured every two Metropolis full-lattice sweep (our EMCS).

The number of EMCS ranges from $10^8$ for $L = 8$ to $7 \times 10^8$ for $L = 64$. In units of the integrated autocorrelation time $\tau$ (for the order parameter) we have more than $10^6 \tau$ for $L = 64$. The data up to $L = 48$ were obtained in Pentium IV clusters (simulation time was roughly equivalent to 1000 days of a single processor). For the largest lattice, data were obtained in the Mare Nostrum computer of the Barcelona Supercomputing Center (simulation time was roughly equivalent to 3000 days of a single processor).

We perform a finite-size scaling analysis, using the quotients method [5,6,20]. In this approach, one compares the mean value of an observable, $O$, in two systems of sizes $L_1$ and $L_2$, at the value of $\beta$ where the correlation length in units of the lattice sizes coincides for both systems. If, for the infinite volume system, $\langle O(\beta) \rangle \propto |\beta - \beta_c|^{-1/\omega}$, the basic equation of the quotient method is

$$Q_{\alpha}^{L_1,L_2}(\beta) \equiv \frac{\langle O(\beta, L_2) \rangle}{\langle O(\beta, L_1) \rangle} \bigg|_{\frac{L_2}{L_1} = \beta_c}$$

$$= (L_2/L_1)^{x_{\alpha}/\nu} \left(1 + A_{\alpha} L_1^{-\omega} + \cdots\right),$$

where the dots stand for higher-order scaling corrections, $\nu$ is the correlation-length critical exponent, $-\omega$ is the (universal) first irrelevant critical exponent, while $A_{\alpha}$ is a non-universal amplitude. In a typical application, one fixes the ratio $s = L_2/L_1$ to 2, and considers pairs of lattices $L$ and $2L$. A linear extrapolation in $L^{-\omega}$ is used to extract the infinite volume limit. One just needs to make sure that the minimum lattice size included in the extrapolation is large enough to safely neglect the higher-order corrections. Of course, any quantity scaling like $\xi$ at the critical point, such as $LU_4$, may play the same role in Eq. (13). However, usually $\xi$ yields smaller scaling corrections than $U_4$.

The extrapolation method based on Eq. (13) is feasible for the antiferromagnetic RP$^2$ model. Unfortunately, for the O(5) model the amplitude $A_{\alpha}$ is surprisingly small. In fact, resummation of the $\varepsilon$-expansion yields $\omega = 0.79(2)$ [13], while blind use of Eq. (13) on our numerical data would predict $\omega \approx 2$. We have then considered an additional correction term, $\tilde{A}_{\alpha} L^{-\sigma}$. The exponent $\sigma$ is an effective way of taking into account a variety of higher-order scaling corrections of similar magnitude (an $L^{-2\omega}$ contribution, subleading universal irrelevant critical corrections, analytic corrections, effects of the non-linearity of the scaling fields, etc. [20]). Its utility will be in that it allow us to give sensible error estimates for the infinite-volume extrapolations, instead of bluntly taking $A_{\alpha} = 0$.

The most precise way of extracting the critical exponent, $\omega$, and the critical point $\beta_c$ is to consider the crossing point of dimensionless quantities such as $\xi/L$ and $U_4$. Indeed, comparing their values in lattices $L_1$ and $L_2$, one finds that they take a common value at

$$\beta_c^{L_2,L_1} = \beta_c + B \frac{1 - (L_2/L_1)^{-\omega}}{(L_2/L_1)^{1/\nu} - 1} L_1^{-\omega - 1/\nu} + \cdots.$$

(14)

The non-universal amplitude $B$ depends on the considered dimensionless quantity. Again, one usually take pairs of lattices $L$ and $2L$, and extrapolates to infinite volume using Eq. (14), maybe performing a joint fit for the crossing points of several dimensionless quantities. Again, for the O(5) model the amplitudes $B$ are exceedingly small, and we need to add to Eq. (14) an analogous higher-order term, where $\sigma$ plays the role of $\omega$, and with amplitude $\tilde{B}$. 
4. Results for the O(5) model

The first step is the location of the critical point and the scaling corrections exponent. In Table 1 we show the crossing points $\beta_c^{L,2L}$ for the dimensionless quantities $\xi_V/L$ and $U_{4,V}$. To study the finite size corrections, we need to fit them to

$$\beta_c^{L,2L} \approx \beta_c + BL^{-\omega - 1/\nu} + \tilde{B}L^{-\sigma - 1/\nu}. \quad (15)$$

Fixing $\tilde{B} = 0$ yields $\omega$ larger than 2 which is unacceptable given the field theory estimate $\omega = 0.79(2)$ [13]. Our interpretation is that $B$ is too small to be observed even with our 6-digit accuracy. We have therefore fixed $\omega = 0.79(4)$ and we have taken as fit parameters $\beta_c$, $B$, $\tilde{B}$ and $\sigma$. We have doubled the field theory error in $\omega$ for safety. To further constrain $\beta_c$ (and $\sigma$), we have performed a joint fit of the crossing points for both $\xi_V/L$ and $U_{4,V}$, with the same $\beta_c$. For this model we always fit for $L \geq 8$. The results are (in all fits reported in this work, the full covariance matrix was used):

$$\beta_c = 1.1813654(19), \quad \sigma = 2.21(17),$$

$$\chi^2/\text{dof} = 7.1/8. \quad (16)$$

Notice that, for using Eq. (15), an estimate of $\nu$ is needed. Fortunately, a rough estimate $\nu \approx 0.78$ (see below) is enough, given the uncertainty in $\omega$ and $\sigma$. As for the amplitudes of the leading correction term, we find

$$B_{\xi_V/L} = 0.004(6), \quad B_{U_{4,V}} = -0.001(3). \quad (17)$$

while the amplitudes $\tilde{B}$ are of order one. We then see that the $L^{-\sigma}$ term is crucial in order to obtain a sensible error estimate in the $L \to \infty$ extrapolation.

At this point we may obtain two universal quantities, $U_{4,V}$ and $\xi_V/L$, namely, the $L \to \infty$ limit of $U_{4,V}$ and $\xi_V/L$ evaluated exactly at the critical coupling. Again, due to the smallness of the leading scaling-correctors, we extrapolated to $L \to \infty$ using the following functional forms:

$$U_{4,V}(\beta_c^{L,2L}, L) \approx U_{4,V} + C_{U_{4,V}} L^{-\omega} + \tilde{C}_{U_{4,V}} L^{-\sigma},$$

$$\xi_V(\beta_c^{L,2L}, L) \approx \frac{\xi_V^*}{L} + C_{\xi_V/L} L^{-\omega} + \tilde{C}_{\xi_V/L} L^{-\sigma}. \quad (18)$$

Our numerical estimates for $U_{4,V}(\beta_c^{L,2L}, L)$ and $\xi_V(\beta_c^{L,2L}, L)/L$ are displayed in the third and fourth columns of Table 1. Although scaling-correctors are tiny, they can be clearly observed. Using Eqs. (18), (19) we obtain

$$\frac{\xi_V^*}{L} = 0.28145(13) \left( \frac{\chi^2}{\text{dof}} = \frac{2.9}{3} \right),$$

$$U_{4,V}^* = 1.06978(5) \left( \frac{\chi^2}{\text{dof}} = \frac{2.8}{3} \right), \quad (20)$$

while the amplitudes of the leading scaling-correctors are

$$C_{\xi_V/L} = 0.002(3), \quad C_{U_{4,V}} = 0.0002(6). \quad (21)$$

To obtain the critical exponents, we consider the operators $\partial \xi_V$ and $\chi_V$, with their associated exponents are $\lambda_{\partial \xi_V} = \nu + 1$ and $\lambda_{\chi_V} = (\nu - \eta_{\chi_V})$. Taking the base 2 logarithm of the quotients, see Eq. (13), we obtain the effective size dependent exponent shown in Table 2. In order to obtain their infinite volume value, we use (13), including an explicit $L^{-\sigma}$ term in the fit:

$$Q_O^{L,2L} = 2^{x_o/\nu} + A_{O} L^{-\omega} + \tilde{A}_O L^{-\sigma}$$

(note that we have absorbed a constant factor $2^{x_o/\nu}$ into the amplitudes $A$ for scaling-correctors). We obtain

$$v = 0.780(2), \quad \sigma = 2.15(19),$$

$$A_{\partial \xi_V} = -0.04(7), \quad \chi^2/\text{dof} = 8.4/8,$$

$$\eta_V = 0.03405(3), \quad \sigma = 2.27(19),$$

$$A_{\chi_V} = 0.0012(14), \quad \chi^2/\text{dof} = 8.5/8,$$
Fig. 1. Size-dependent estimators for the anomalous dimensions of the O(5) model as obtained from \((L, 2L)\) pairs, versus \(L^{-\omega}\). We plot estimates from the crossing points of \(U_{4, V}\) and of \(\xi_{V}/L\). We use the value \(\omega = 0.79\), from Ref. [13].

\(\eta_{T} = 1.3307(5), \quad \sigma = 2.24(19), \quad A_{\chi T} = -0.0053(12), \quad \chi^{2}/\text{dof} = 9.6/8. \) (23)

Less than a 5% of the total error is due to the error in \(\omega = 0.79(4)\) for both \(\nu\) and \(\eta_{V}\). For \(\eta_{T}\) it is about a 30%. There are two points to be made about the extrapolation:

- The O(5) model is not an improved action [23] (in the sense of exactly vanishing leading scaling-corrections), since \(A_{\chi T}\) is clearly non-zero (this is also illustrated in Fig. 1). Had we not considered the tensorial operators, this would have been completely missed.
- It is somehow disappointing to compare the accuracy of the effective exponent \(\nu\) in Table 2 with the error in the extrapolation (23). Indeed, could we safely set \(A_{\beta_{V}} = 0\), the final result would have been \(\nu = 0.7813(4)\).

5. Results for the antiferromagnetic RP² model

As we said before, qualitative arguments suggest that the antiferromagnetic RP² model belongs to the O(5) universality class. Our aim is to make the most astringent possible test of this hypothesis, thus we perform here an update of a previous study [6] of the RP² critical quantities. We report here largely improved estimates for critical coupling and exponents. Furthermore, we give estimates for the dimensionless quantity \(U^{*}_{4, V}\), that can be directly compared with the \(U^{*}_{4, V}\) obtained for the O(5) model.

In this case, the extrapolation to the infinite volume limit is more standard (see, for instance, [24]) than for the O(5) model, because the amplitude of the leading scaling-corrections are much larger in most cases. To estimate \(\omega\) and \(\beta_{V}\), we consider pair of lattices \(L\) and \(2L\), performing a joint fit to Eq. (14) of the crossing points of all four dimensionless quantities, imposing a common value of \(\beta_{V}\) and \(\omega\) (see Fig. 2). To control for systematic errors due to higher-order corrections, we follow the following procedure. We perform the fit using data for \(L \geq L_{\text{min}}\), seeking a value of \(L_{\text{min}}\) where a reasonable value of \(\chi^{2}/\text{dof}\) is found. Furthermore,
we require that the fit performed for $L > L_{\text{min}}$ yield compatible results. In that case, we report the central value from the $L \geq L_{\text{min}}$ fit, but taking the enlarged errors from the $L > L_{\text{min}}$ fit. We found that $L_{\text{min}} = 12$ is enough for the extrapolation of $\beta_c$. We obtain:

$$\beta_c = -2.40899(13),$$

$$\omega = 0.78(4), \quad \chi^2/\text{dof} = 8.5/10. \quad (24)$$

Once we have determined $\omega$, we proceed to extrapolate $U_4^{s,s}$, and the critical exponents, using the analog of Eqs. (18), (19), (22) without the effective $L^{-\sigma}$ term. Although one could consider all four types of crossing points, $\beta_{L,2L}^c$, the resulting quotients would be highly correlated, making joint fits scarcely useful. We concentrate on the crossing point of $\xi^s/L$, which seems the most natural quantity, as we are dealing with an antiferromagnetic model and it can be obtained using only the two-points correlation function. We have checked that other choices for $\beta_{L,2L}^c$ yield compatible results, with slightly larger errors. Our extrapolations are shown together with the effective $L$-dependent estimates in Table 3. Error estimates in the extrapolation include the effect of the uncertainty in $\omega$. For exponent $\nu$, scaling corrections are completely buried in the statistical errors. We extrapolated with a simple linear fit, using $L_{\text{min}} = 8$. The situation is rather different for $\eta^s$. For that exponent, enlarging $L_{\text{min}}$ systematically increases the asymptotic estimate. On the other hand, a fit quadratic in $L^{-\omega}$ yields a linear term compatible with zero. The linear extrapolation with $L_{\text{min}} = 16$ is identical to the quadratic extrapolation from $L_{\text{min}} = 8$. This is the result indicated in Table 3. As for $\eta^f$, we have rather strong leading scaling corrections. Indeed,
Fig. 3. Phase diagram of the extended antiferromagnetic $\mathbb{R}P^2$ model, Eq. (26).

a fit linear in $L^{-\omega}$ yields basically identical results for $L_{\text{min}} = 8$ and $L_{\text{min}} = 12$ (this is the result reported in Table 3). Furthermore, a fit quadratic in $L^{-\omega}$ including all points, yielded $\eta_f = 1.331(5)$. The extrapolation for $U_{4,*}^{f}$ is equally simple.

The extrapolation for other scale-invariant quantities, without an obvious correspondent in the $O(5)$ model, are:

$$\frac{\xi_{s,*}}{L} = 0.5379(17), \quad \frac{\xi_{f,*}}{L} = 0.2236(15),$$

$$U_{4,*}^{f} = 1.3114(6). \quad (25)$$

6. Next nearest neighbors coupling

A rather subtle question regards the symmetry of the low-temperature $\mathbb{R}P^2$ antiferromagnetic phase [6,9]. A way of investigating this problem is to study the enlarged action

$$S = -\beta_1 \sum_{\langle i,j \rangle} (\vec{v}_i \cdot \vec{v}_j)^2 - \beta_2 \sum_{\langle i,j \rangle} (\vec{v}_i \cdot \vec{v}_j)^2,$$  \quad (26)

where an additional second-neighbors coupling is considered.

The phase diagram for $\beta_1 < 0$ (Fig. 3) contains the following regions (spins are classified as even or odd, according to the parity of $x_i + y_i + z_i$):

- PM: the usual (paramagnetic) disordered state, where the $O(3)$ symmetry of the action (26) is preserved.
- O(2): (say) even spins fluctuate almost parallel to (say) the $Z$ axis, with random sense (local $Z_2$ symmetry), while odd spins fluctuate in the perpendicular plane (global $O(2)$ symmetry).
- O(1): two sublattices with ferromagnetic ordering in perpendicular directions, with random sense (the local $Z_2$ symmetry, $\vec{v}_i \rightarrow -\vec{v}_i$ is always preserved).
- Skyrmion/flux: the spins are parallel to the diagonals of the unit cube, so that they point out from/to the center (i.e., the propagator show three peaks at $p_0 = (\pi, \pi, 0)$ and permutations). It is interesting to note the vectorial version of this phase appear in models for colossal magnetoresistance oxides [25].

The most relevant results can be summarized as follows:

- We have obtained critical exponents for several points along the PM–O(2) critical lines, with significantly less accuracy than for the $\beta_2 = 0$ model. No variation was observed within errors.
- The O(2)–O(1) critical line is repelled from the $\beta_2 = 0$ axis by the second-neighbors coupling. We interpret this as a competition with the order-from-disorder mechanism [6,9] behind the PM–O(2) transition.
Table 4
Summary of infinite-volume estimates for the 3D antiferromagnetic $\mathbb{RP}^2$, O(5) and O(4) models. We call $\eta'$ to $\eta'$ for $\mathbb{RP}^2$ and to the $\eta_L$ for O(N) models. FT stands for field theory.

- A naive analysis suggests that the O(2)–O(1) transition line should belong to the XY universality class (consider first the limit $\beta_1 = -\infty$, then the identity $\cos^2 \theta = (1 + \cos 2\theta)/2$ for the less ordered face-centered cubic sublattice). However, we have found that this transition line is first-order, as revealed by the double-peaked histogram of the second neighbors energy. We are able to estimate a non-zero latent-heat up to $\beta_1 = -6$. At $\beta_1 = -4$ the double-peak structure is still easy to observe on small lattices. We presume that the whole line is first-order, although it could become very weak.
- The skyrmion–PM transition lines turned out to be first-order at all the checked points.
- Note that at $\beta_1 = 0$, we have two decoupled ferromagnetic $\mathbb{RP}^2$ models on the face-centered cubic lattice (a model showing first-order transition, well known in the liquids-crystal context [26]). We should remark that a precise location of the triple point O(2)–O(1)–PM is very difficult to achieve.

7. Conclusions

We have obtained high accuracy estimates of critical exponents and other universal quantities for the three-dimensional O(5) and the antiferromagnetic $\mathbb{RP}^2$ models, by means of Monte Carlo simulation, finite-size scaling analysis and careful infinite-volume extrapolation.

In the case of the O(5) model the coupling to the leading irrelevant operator is rather weak, but non-vanishing, and one needs to consider higher-order scaling corrections to obtain sensible error estimates. In spite of that, our estimates for the critical coupling and the anomalous dimensions for the vector and tensor representations improve significantly over previous work (see Table 4).

For the $\mathbb{RP}^2$ model, the leading scaling corrections are sizeable. It is amusing that we are able to obtain numerically (for the first time, we believe) an estimate for the (universal) scaling-correction exponent $\omega = 0.78(4)$, of accuracy comparable to the perturbative field-theoretical estimate [13] $\omega = 0.79(2)$. As Table 4 shows, within the achieved accuracy, both models seem to belong to the same universality class (for comparison, we also show results from the O(4) universality class). To conclude this, one needs to accept that in the $\mathbb{RP}^2$ model, the wavefunction renormalization for the propagator pole at $p_0 = (\pi, \pi, \pi)$ is as for the O(5) fundamental field, while at $p_0 = (0, 0, 0)$ is as for the O(5) tensor field.

We have also obtained the phase-diagram of the $\mathbb{RP}^2$ model extended with a second nearest-neighbors interaction. We have found a rich phase diagram.

Acknowledgements

We are indebted with Juan Jesús Ruiz-Lorenzo for discussions. We are grateful to the Barcelona Supercomputing Center, for allowing us to use Mare Nostrum in its installation phase. Isabel Campos was crucial in this respect. About a third of the total simulation time was obtained from the cluster of the Instituto de Biocomputación y Física de Sistemas Complejos, in Zaragoza, and other computing resources of the Departamento de Física Teórica of Universidad de Zaragoza. We acknowledge partial financial support from Ministerio de Educación y Ciencia (Spain) though research contracts BFM2003-08532 and FIS2004-05073.
