We study the thermodynamics of the full version of the Dicke model, including all the possible values of the total angular momentum $j$, with both microcanonical and canonical ensembles. We focus on both the excited-state quantum phase transition, appearing in the microcanonical description of the maximum angular momentum sector, $j = N/2$, and the thermal phase transition, which occurs when all the sectors are taken into account. We show that two different features characterize the full version of the Dicke model. If the system is in contact with a thermal bath and is described by means of the canonical ensemble, the parity symmetry becomes spontaneously broken at the critical temperature. In the microcanonical ensemble, and despite that all the logarithmic singularities which characterize the excited-state quantum phase transition are ruled out when all the $j$ sectors are considered, there still exists a critical energy (or temperature) dividing the spectrum into two regions: one in which the parity symmetry can be broken, and another in which this symmetry is always well defined.

I. INTRODUCTION

Quantum phase transitions (QPTs) and critical phenomena play an important role in the study of many-body quantum systems [1]. During the last decade, a new kind of phase transition has been studied in depth: the excited-state quantum phase transition (ESQPT) [2–6]. In contrast to QPTs, which describe the nonanalytic evolution of the ground state energy as a function of a control parameter, ESQPTs refer to a similar nonanalytic behavior that takes place at a certain critical energy $E_c$, when the control parameter responsible for the QPT is kept fixed [3,7].

ESQPTs have been theoretically studied in many kinds of quantum systems. Paradigmatic examples are the Lipkin-Meshkov-Glick (LMG) model [8,9], the Dicke and Tavis-Cummings models [10,11], the interacting boson model [12], the molecular vibron model [13], atom-molecule condensates [14], and the kicked-top [15] or the Rabi model [16]. Also, a number of experimental results have been recently reported in molecular systems [17], superconducting microwave billiards [18], and spinor condensates [19]. However, and despite the intense research performed during the last couple of years, some important questions still remain open. The most important one is whether the critical energy does separate two different phases in the spectrum. Contrary to what happens in quantum and thermal phase transitions, there are no clear traces of order parameters in ESQPTs. Though many physical observables become singular at the critical point, it seems impossible to find a magnitude which is zero at one side of the transition and remains different from zero at the other (see, for example, Ref. [5]). A recent proposal to characterize the transition relies on how the values of the physical observables change with energy [20]. This idea allows us to identify two different regions in the spectrum, but it does not provide an easy way to distinguish different phases just by measuring an appropriate observable. Another recent proposal relies on symmetry breaking. A number of quantum systems showing ESQPTs are characterized by a discrete $Z_2$ symmetry which can be broken at one side of the transition, but not at the other. From fundamental physical reasons this seems a promising idea. First, it links ESQPTs with the breakdown of a certain symmetry, following a line of thought similar to the theory of thermal phase transitions. Second, this fact entails measurable dynamical consequences if a thermodynamic process is performed from a symmetry-breaking initial condition: the symmetry of the final equilibrium state remains broken only if the final energy is at the corresponding side of the transition, whereas the symmetry is restored on the contrary [21,22]. However, if the initial condition has a well-defined value of this symmetry, nothing similar happens when crossing the critical energy. In other words, crossing an ESQPT does not entail a spontaneous breakdown of the corresponding symmetry under any circumstances; the occurrence of this phenomenon depends on the details of the protocol.

Notwithstanding, the possible links between ESQPTs, thermal phase transitions, and the breakdown of certain fundamental symmetries of the system deserve to be explored. ESQPTs occur when the system is kept isolated from any environment and thus can be described by means of the microcanonical ensemble. On the contrary, thermal phase transitions take place at a certain critical temperature $\beta_c$ and are usually described considering that the critical system is in contact with a thermal bath, that is, by means of the canonical ensemble [23]. But, as microcanonical and canonical descriptions become equivalent in the thermodynamical limit $N \rightarrow \infty$, where $N$ is the number of particles of the critical system, it is logical to expect that critical energy $E_c$ and critical temperature $\beta_c$ provide analogous information about the system. If we describe the critical system by means of the canonical ensemble, we should expect that the critical energy $E_c$ of the ESQPT corresponds to the internal energy $U = -\partial \ln Z/\partial \beta$, evaluated at the critical temperature $\beta_c$, where $Z$ is the canonical partition function. And if the system is described by means of the microcanonical ensemble, the critical temperature $\beta$ should correspond to the microcanonical temperature $\beta = \partial \ln \rho(E)/\partial E$, evaluated at the critical energy $E_c$, where $\rho(E)$ is the density of states. However, all the facts
discussed below suggest just the opposite—that thermal and excited-state quantum phase transitions are totally different. Probably this is due to the fact that ESQPTs take place in systems with a small number of semiclassical degrees of freedom, implying that the size of the corresponding Hilbert space grows as $N^j$, where $j$ is the number of degrees of freedom; the larger the number of degrees of freedom, the less important are the consequences of the ESQPT [5]. On the contrary, thermal phase transitions require an exponential growth of the size of the Hilbert space with the number of particles in order to ensure that intensive thermodynamical quantities, like the entropy per particle, $S/N$, or the Helmholtz potential per particle, $F/N$, are well defined in the thermodynamical limit. Hence, it is not clear even whether the correspondence between thermal and excited-state quantum phase transitions exists, or whether they are different phenomena occurring under different physical circumstances. Indeed, it is shown in Ref. [24] that, for collective systems, the thermodynamical limit $N \to \infty$ does not coincide with the true thermodynamic limit unless the number of degree of freedom, $f$, also tends to infinity. So, ESQPTs and thermal phase transitions appear for different asymptotic regimes of $N$ and $f$. (We notice that, during the progress of this work, a similar analysis, but with a different aim, was performed in the generalized Dicke model, showing that it shows two different kinds of superradiance [25].)

In this work we tackle this task by studying, both analytically and numerically, the Dicke model. It describes a system of $N$ two-level atoms interacting with a single monochromatic electromagnetic radiation mode within a cavity [26]. It is well known from the 1970s that this model exhibits a thermal phase transition [27,28]. However, recently it was also found that it undergoes an ESQPT [10] alongside the QPT [29]. This kind of QPT has been experimentally observed in several systems [30], and the Dicke model itself can be simulated by means of a Bose-Einstein condensate in an optical cavity [31]. All these facts make this model the best one to study the relationship between thermal and excited-state quantum phase transitions.

Up to now, the majority of works on the Dicke model, including the ones dealing with QPTs and ESQPTs (except Ref. [25], as we pointed out above), were done in the subspace with maximum pseudospin sector $j = N/2$, in which the ground state is included. This restriction is enough to properly describe the recent experimental results [31] and also to study all the consequences of the QPT. Furthermore, ESQPTs have been observed in the subspace with $j = N/2$, which can be described by means of a semiclassical approximation with just two degrees of freedom in the thermodynamic limit $N \to \infty$. However, it is well known that this restriction destroys the thermal phase transition [32]; the fact that the atomic subspace grows linearly with $N$ in the $j = N/2$ sector makes it impossible to properly define the entropy $S$ or the Helmholtz potential $F$ and, therefore, precludes the thermal phase transition. In this work we deal with the complete Dicke model, including all the $j$ sectors. This is equivalent to increasing the number of degrees of freedom in the system that eventually go to infinity in the thermodynamical limit. Contrary to the seminal papers on the thermal phase transition [27,28], we study the thermodynamics of this model in the microcanonical ensemble, considering the system isolated instead of being in contact with a thermal bath. This point of view allows us to study the possible connections between the excited-state and the thermal phase transitions. In particular, we show that each $j$ sector displays the same kind of ESQPT, provided that the coupling constant is large enough (see below for a detailed discussion regarding this condition), but each one having a different critical energy $E_c$. Paradoxically, this fact, together with the different weight of each $j$ sector in the spectrum of the complete Dicke model, destroys most of the signatures of the ESQPT and somehow surprisingly entails the appearance of the typical signatures of thermal phase transitions, like the existence of an order parameter. In particular, we show that the collective contribution of all the $j$ sectors rules out the logarithmic singularities in the derivatives of the density of states, $\rho(E)$, and the third component of the angular momentum, $J_z$, characteristic of the ESQPT. However, one of the most important signatures of the ESQPT survives. The parity symmetry of the Dicke model (see below for details) can be still broken below the critical energy $E_c$, which exactly coincides with the canonical internal energy $U$, evaluated at the critical temperature of the thermal phase transition, $\beta_c$. In the microcanonical ensemble, that is, if the system remains isolated from any environment, the expectation value of a symmetry-breaking observable, like $J_z$, is always zero above $E_c$, but it can be different from zero below; its particular behavior depends on the initial condition. If the system is in contact with a thermal bath, and is described by means of the canonical ensemble, a small symmetry-breaking term $\epsilon J_z$ produces that $\langle J_z \rangle \neq 0$, even if we take the limit $\epsilon \to 0$ after the thermodynamical limit is done. In other words, the symmetry-breaking observable $J_z$ plays here the same role as the magnetization in the Ising model; it is an order parameter of the transition and shows that the parity symmetry becomes spontaneously broken below the critical temperature. On the other hand, the behavior of an isolated system is different. As it happens if only the highly symmetric sector, $j = N/2$, is taken into account, the parity symmetry remains broken below the critical energy $E_c$ of the ESQPT only if this symmetry is yet broken in the initial condition. In other words, the behavior of the system is expected to be different depending on whether the system is heated by means of the Joule effect, or it is in contact with a thermal bath.

This paper is organized as follows. In Sec. II we present the Dicke model. In Sec. III we review the thermodynamics of the Dicke model restricted to the highly symmetric Dicke states, $|j = N/2, M\rangle$. We compare the results provided by the microcanonical and canonical ensembles, and we analyze the symmetry-breaking character of the ESQPT. In Sec. IV we perform a similar analysis including all the $j$ sectors; we show that an ESQPT occurs in each $j$ sector. We also show that the symmetry-breaking nature of the transition is still present and leads to spontaneous symmetry breaking if the system is in contact with a thermal bath. In addition, we study the main physical differences between the system in isolation and in contact with a thermal bath. Finally, we extract the more relevant conclusions in the last section.

II. THE DICKE MODEL

The Dicke model describes the interaction of $N$ two-level atoms of splitting $\omega_0$ with a single bosonic mode of frequency
where \( a \) and \( a^\dagger \) are the usual creation and annihilation operators of photons, and \( J = (J_x, J_y, J_z) \) is the Schwinger pseudospin representation of the \( N \)-two-level atom system, that is, the total angular momentum of a system of \( N \) spin-1/2 particles. This Hamiltonian has two conserved quantities. The first one is \( \Pi = \exp (i \pi [J_x + J_y + a^\dagger a]) \), due to the invariance of \( H \) under \( J_x \to -J_x \) and \( a \to -a \); as this is a discrete symmetry, \( \Pi \) has only two different eigenvalues, \( \Pi | \pm \rangle = \pm | \pm \rangle \), and it is usually called parity. The second one is the total angular momentum \( J^2 \) of the \( N \) spin-1/2 particles. This entails that the Hamiltonian (1) is block diagonal in \( J^2 \), and hence each sector is totally independent of the others. The main dynamical consequence is that each \( j \) sector evolves independently in any protocol keeping the Dicke model isolated from any heat bath. Furthermore, as the recent experimental realizations of this protocol keeping the Dicke model isolated from any heat bath. This model shows QPTs, ESQPTs, and thermal phase transitions. In the following paragraphs we summarize the known results.

### III. THE CASE WITH \( j = N/2 \)

In this section, for the sake of completeness, we review the thermodynamics of the Dicke model restricted to the highly symmetric Dicke states, \( | j = N/2, M \rangle \). This configuration corresponds to a two-level system in which \( N \) bosons can occupy either the upper or the lower level [32]. It was recently explored by means of a Bose-Einstein condensate in an optical cavity [31]. First of all, we present the density of states, \( \rho(E) \), which is computed by means of the microcanonical ensemble, and later we show the same \( \rho(E) \) but consider the calculation in the canonical ensemble. These are well-established results. Finally, we compare both approaches and get some conclusions.

#### A. Microcanonical ensemble

Let us consider that the system is thermally isolated and that we perform the following procedure: First, we freeze the system, keeping fixed all the external parameters of the Hamiltonian, until it is equilibrated at \( T \sim 0 \). This entails that the ground state, which always corresponds with the sector of maximum angular momentum \( j = N/2 \), is the only populated energy level. Second, we perform a quench, abruptly changing one of the external parameters. Then, if the system remains thermally isolated from the environment, the unitary evolution is totally captured by the sector with \( j = N/2 \). Hence, all the thermodynamic results after the system is equilibrated at the final values of the external parameters should be obtained from a microcanonical calculation with fixed \( j = N/2 \). This calculation can be completed by means of a semiclassical approximation, following different methods [11,33,34]. Here, we follow the method in Ref. [34].

Considering \( \omega = \omega_0 = 1 \), the density of states reads

\[
\rho(E,j) = \begin{cases} 
\frac{2j}{J} & \text{if } E/N > 1/2, \\
\frac{2j}{\sqrt{2}(1 + y^2)} & \text{if } -1/2 \leq E/N \leq 1/2, \\
\frac{2j}{\pi \sqrt{2} (1 - y^2)} & \text{if } E/N < -1/2, 
\end{cases}
\]

where

\[
y_- = \frac{-j + \sqrt{J} \sqrt{1 + 8E \lambda^2 + 16j \lambda^4}}{4j^2 \lambda^2}
\]

and

\[
y_+ = \frac{-j + \sqrt{J} \sqrt{1 + 8E \lambda^2 + 16j \lambda^4}}{4j^2 \lambda^2}.
\]

For the third component of the angular momentum, we obtain

\[
\frac{J_\lambda(E,j)}{j} = \begin{cases} 
0 & \text{if } E/N > 1/2, \\
\frac{2j}{\pi \sqrt{2} (1 - y^2)} & \text{if } -1/2 \leq E/N \leq 1/2, \\
\frac{2j}{\pi \sqrt{2} (1 + y^2)} & \text{if } E/N < -1/2. 
\end{cases}
\]

Finally, for the first component of the angular momentum and considering that the parity is totally broken in the initial state,

\[
\frac{J_x(E,j)}{j} = \begin{cases} 
0 & \text{if } E/N > -1/2, \\
\pm \frac{2j}{\pi \sqrt{2} (1 - y^2)} & \text{if } E/N < -1/2, 
\end{cases}
\]
where the sign depends on the initial state. This expression has been obtained taking into account only one of the two disjoint parts in which the semiclassical phase space is divided for \( \lambda > \lambda_c \). At \( E = -N/2 \) [21]. If the initial state has a well-defined parity, both parts of the semiclassical phase space are populated, giving rise to \( \langle J_z \rangle = 0 \).

These results show that an ESQPT happens at \( E_c/N = -1/2 \) [10,11,21,34]. There are singular points for both \( \rho(E,j) \) and \( J_z(E,j) \); the derivatives of both magnitudes show a logarithmic divergence at \( E_c \). The reason for this behavior is the following: the density of states, Eqs. (2), is proportional to the size of the phase space available to the system,

\[
\rho(E,j) = C \int dq_1 dq_2 dp_1 dp_2 \delta(E - H(q_1, q_2; p_1, p_2)),
\]

where \( q_1 \) and \( q_2 \) denote the semiclassical coordinates, \( p_1 \) and \( p_2 \) denote the semiclassical momenta, and \( C \) is a normalization constant (see, for example, Ref. [34]). The key point is that despite that this semiclassical system is finite, it describes the quantum Dicke model in the thermodynamical limit, \( N \to \infty \), and it has just \( f = 2 \) degrees of freedom. Furthermore, every quantum system showing an ESQPT is equivalent to a semiclassical system with a finite number of degrees of freedom (see, for example, Ref. [5]). As a consequence, nonanalyticities in the quantum density of states are linked to stationary points in the corresponding semiclassical model, and the geometric properties of such stationary points determine the nature of the corresponding singularities. In particular, systems with \( f = 1 \) semiclassical degrees of freedom show logarithmic singularities in the density of states, as well as in certain physical observables at the critical energy of the ESQPT, \( E_c \); systems with \( f = 2 \) degrees of freedom show the same kind of singularities in the derivatives of the same magnitudes [5]. Results for a higher number of degrees of freedom have been recently published, showing that the larger \( f \), the higher the derivative in which the logarithmic singularity takes place [35].

Also, if the parity symmetry is broken in the initial state, \( J_z(E,j) \) acts like an order parameter for the ESQPT; that is, it shows a finite jump at \( E_c \), from \( \langle J_z \rangle \neq 0 \) to \( \langle J_z \rangle = 0 \) [21]. On the contrary, initial conditions with well-defined positive (or negative) parity do not suffer any change when crossing the ESQPT.

Another singular point is located at \( E_c/N = 1/2 \), but its critical character is controversial [11,34]. Above this energy, \( \rho(E) = 1 \) and \( \langle J_z \rangle = 0 \) due to the ergodic character of the atomic motion (now the whole phase space is accessible to the system). Despite that this point is not usually identified as an ESQPT, it has some of the features of a second-order phase transition. First, there exists an order parameter identifying two different phases: for \( E < N/2 \), \( \langle J_z \rangle \neq 0 \), whereas \( \langle J_z \rangle = 0 \) for \( E > N/2 \). Second, there is a discontinuity in the derivative of \( \rho(E) \), that is, in the second derivative of the cumulated level density, \( N(E) \). We come back to this discussion in Sec. IV. Numerical results illustrating these facts are shown later.

### B. Canonical ensemble

The same kind of calculation can be performed in the canonical ensemble, considering that the system weakly interacts with a thermal bath which commutes with \( J^2 \). Following Ref. [32] we can obtain the partition function

\[
Z(N,\beta) = \frac{1}{\beta} \int_{-\infty}^{\infty} dx \exp(-\beta\omega x^2) \int_{-\infty}^{\infty} dy \exp(-\beta\omega y^2) Z_s(N,\beta),
\]

where

\[
Z_s(N,\beta) = \sum_{m=-N/2}^{N/2} \exp(-\beta m\sqrt{\omega_0^2 + 4\lambda^2 x^2/n}).
\]

The final result is

\[
Z(N,\beta) = \sqrt{\frac{n}{\beta N,\beta}} \int_{-\infty}^{\infty} dx \exp \left[ -\beta \left( \omega x^2 + \frac{n}{2} \omega_0^2 + 4\lambda^2 x^2/n \right) \right] \times \exp \left( \beta(n+1)\sqrt{\omega_0^2 + 4\lambda^2 x^2/n} - 1 \right).
\]

There is no way to write this integral in terms of simple analytical functions, but it can be evaluated numerically to obtain results for precise values of all the external parameters \( \omega, \omega_0, \) and \( \lambda \). Furthermore, other thermodynamic results can be obtained from the partition function

\[
\langle E \rangle = -\frac{\partial \ln Z}{\partial \beta},
\]

\[
\langle J_z \rangle = -\frac{1}{\beta} \frac{\partial \ln Z}{\partial \omega_0}.
\]

In all the cases \( \langle J_z \rangle = 0 \).

It has been shown that there is no thermal phase transition under these circumstances [32]. In other words, microcanonical and canonical ensembles give rise to totally different results. If the system remains thermally isolated there exists a critical energy \( E_c = -N/2 \) at which a nonanalyticity occurs, giving rise to a number of dynamical (and observable) consequences [10,21]. On the other hand, if the system is put in contact with a thermal bath, everything changes smoothly with the temperature \( \beta \); in particular, nothing happens at the critical temperature \( \beta_c \), given by \( \langle E(\beta_c) \rangle = -N/2 \).

### C. Results

In this section, we compare the results of both the microcanonical and the canonical calculations, for a system with \( \omega = \omega_0 = 1 \), \( \lambda = 3\lambda_c = 1.5 \), and \( N = 1 \times 10^5 \). All the results are plotted versus the scaled energy \( E/N \). For the canonical calculation, this energy is obtained directly from Eq. (11).

In Figs. 1, 2, and 3 we depict the results for \( \langle J_z \rangle, \langle dJ_z/dE \rangle, \) and \( \langle J_z \rangle/N \), respectively. In the first two cases, we show both the microcanonical (solid green points) and the canonical (dashed red line) calculations; in Fig. 3, we show just the microcanonical calculation, because \( \langle J_z \rangle = 0 \) in the canonical ensemble. In all the cases we show the critical
energy of the ESQPT, \( E_c/N = -1/2 \), by means of a vertical dashed line.

As a general result, we can observe that the behavior of the Dicke model in the \( j = N/2 \) sector is totally different depending whether it is thermally isolated or in contact with a thermal bath. In the first case, we can see neat signatures of the ESQPT (a singular point in \( \langle d J_z/dE(E_c) \rangle \) or the crossing from \( \langle J_z(E) \rangle \neq 0 \) to \( \langle J_z(E) \rangle = 0 \), if the parity symmetry is broken in the initial state). In the second one, no traces of such phenomena are present. The reason behind this result is that the microcanonical density of states grows linearly with \( N \). This entails that the thermodynamic magnitudes that should be extensive, like the entropy, \( S \), or the Helmholtz free energy, \( F \), grow with ln \( N \), and therefore \( S/N \to 0 \) and \( F/N \to 0 \) in the thermodynamic limit. The main consequence is that the different ensembles are not equivalent in the thermodynamic limit, and that thermodynamics in this system is far from usual, and hence the results for the different statistical ensembles do not coincide. As it is pointed out in Ref. [24] this is due to the finite number of (semiclassical) degrees of freedom that the system has in the thermodynamic limit, \( N \to \infty \).

FIG. 2. \( dJ_z/dE \) for the microcanonical ensemble (solid green points) and the canonical ensemble (dashed red line). The vertical dashed line shows the energy of the ESQPT.

IV. THE FULL DICKE MODEL

In this section, we perform a similar analysis as the former one, but now including all the \( j \) sectors in the calculation. From a semiclassical point of view, this entails that the number of degrees of freedom, \( f \), also goes to infinity in the thermodynamical limit.

A. Microcanonical ensemble

If we consider that the system is thermally isolated, we can follow the same procedure as for the case with \( j = N/2 \), taking into account that each \( j \) sector is totally independent of the others. In other words, we can rely on the semiclassical approximation for each \( j \) sector and then collect all these results. Note, however, that the semiclassical approximation only gives good results for large values of the total number of two-level atoms, \( N \). Hence, our procedure is questionable for sectors with low values of \( j \) and, in particular, for the \( j = 0 \) sector. This issue is discussed in detail later on.

To profit from the results obtained in the previous section, we proceed in the following way. The full Dicke model reads

\[
H = \omega a^\dagger a + \omega_0 J_z + \frac{2\lambda}{\sqrt{N}} J_z(a + a^\dagger). \quad (13)
\]

Considering that this Hamiltonian is block diagonal in a \( |j,M \rangle \) basis, the previous equation can be written as follows:

\[
H_j = \omega a^\dagger a + \omega_0 J_z + \frac{2\lambda}{\sqrt{2j}} \sqrt{\frac{2j}{N}} J_z(a + a^\dagger), \quad (14)
\]

where \( H_j \) denotes the Hamiltonian \( H \) in the sector with total angular moment equal to \( j \). Thus, we can define an effective coupling constant for each \( j \) sector, \( \lambda_{\text{eff}}^j = \lambda \sqrt{2j/N} \), giving rise to

\[
H_j = \omega a^\dagger a + \omega_0 J_z + \frac{2\lambda_{\text{eff}}^j}{\sqrt{2j}} J_z(a + a^\dagger). \quad (15)
\]

From this result we conclude that the Hamiltonian of each \( j \) sector, \( H_j \), is formally identical to the one of the highly symmetric sector, \( j = N/2 \), but with a different effective coupling \( \lambda_{\text{eff}}^j \).
With this in mind, we proceed to discuss the presence of ESQPTs in each \( j \) sector. From the results derived in Sec. III A, we conclude the following:

1. ESQPT appears if \( \lambda > \lambda_c = \sqrt{\omega_0 \omega_2} / 2 \). This entails that each \( j \) sector requires a different coupling constant to show the ESQPT, and the smaller the value of \( j \), the larger the coupling:

\[
\lambda_c^{(j)} = \sqrt{\frac{N \omega_0 \omega_2}{8}}.
\] (16)

Therefore, the \( j = 0 \) sector does not exhibit an ESQPT in any case \((\lambda_c^{(j)} \to \infty)\), and the lower values of \( j \) require such large coupling constants for having ESQPTs that these transitions are restricted to the larger values of \( j \) in all the practical cases.

2. The critical energy for each sector is located at \( E_c^j = -j/N \), and the energy of the other singular point at \( E_s^j = j/N \). Thus, the lower \( j \), the smaller the energy band between these two singular points. If \( j \to 0 \) with a coupling constant large enough for the ESQPT to occur, the band shrinks to a single point located at \( E/N = 0 \).

3. For any finite value of the coupling strength in the superradiant phase, \( \lambda > \lambda_c \), the dynamics of the full Hamiltonian is the result of collecting all the \( j \) sectors, with both critical and noncritical behavior.

Considering that each \( j \) sector is totally independent of the others, the density of states for the full Hamiltonian can be obtained as

\[
\rho(E) = \sum_{j=0}^{N/2} g(N,j) \rho(E,j),
\] (17)

where \( g(N,j) \) is the degeneracy of each \( j \) sector, and \( \rho(E,j) \) is given by Eqs. (2).

The degeneracy is obtained as the number of ways in which a set of \( N \) spin-1/2 particles can give rise to a total angular momentum \( j \). The result is

\[
g(N,j) = \frac{1 + 2j}{1 + j + N/2} \left( \frac{N}{N/2 - j} \right).
\] (18)

To make easier the analytical calculations, it is preferable to work with an alternative version of this expression. Instead of working with \( j/N \), we consider the variable \( x = j/N \), which can be taken as a continuous variable \( x \in [0,1/2] \) in the thermodynamical limit, \( N \to \infty \). Also, we write the combinatorial numbers in terms of the \( \Gamma \) function, and therefore we obtain a continuous function \( g(N,x) \) for any finite (but large) value of \( N \),

\[
g(N,x) = \frac{(1 + 2Nx) \Gamma(N+1)}{\Gamma(1+1/2 - Nx) \Gamma(2+N/2+Nx)}.
\] (19)

Hence, the total density of states is given by

\[
\rho(E,N) = \int_0^{1/2} dx \ g(N,x) \rho(E,N,x).
\] (20)

We can apply the same procedure to the expected values of \( J_z \) and \( J_x \), obtaining

\[
J_z(E,N) = \frac{1}{\rho(E,N)} \int_0^{1/2} dx \ g(N,x) \rho(E,N,x) J_z(E,N,x),
\] (21)

with \( J_z(E,N,x) \) given by Eq. (5) and

\[
J_x(E,N) = \frac{1}{\rho(E,N)} \int_0^{1/2} dx \ g(N,x) \rho(E,N,x) J_x(E,N,x),
\] (22)

with \( J_x(E,N,x) \) given by Eq. (6). All these integrals have to be performed numerically since it is not possible to get analytical expressions.

As it has been pointed out before, this procedure assumes that all the \( j \) sectors can be properly described by means of the semiclassical approximation, and this is not completely true. Therefore, the goodness of the final result critically depends on the shape of Eq. (19). If the subsequent integrals are dominated by sectors with \( j \) large enough, we can rely on our procedure; if they are dominated by the lowest \( j \) sectors, the procedure is not going to work. So, prior to presenting the numerical results, we study here the shape of the function \( g(N,x) \). Its maximum can be obtained by solving the equation \( dg(N,x)/dx = 0 \). An asymptotic expansion when \( N \to \infty \) and a Taylor expansion around \( x = 0 \) show that this maximum is located at

\[
x_{\text{max}} = \frac{1}{2\sqrt{N}} - \frac{1}{2N} + O\left(\frac{1}{N^{3/2}}\right).
\] (23)

This result implies two apparently contradictory consequences. First, the maximally degenerated \( j \) sector is

\[
j_{\text{max}} = \frac{\sqrt{N}}{2} - \frac{1}{2} + O\left(\frac{1}{\sqrt{N}}\right).
\] (24)

Hence, \( j_{\text{max}} \to \infty \) in the thermodynamical limit, and consequently the semiclassical approximation used to derive Eqs. (2), (5), and (6) is expected to work provided that \( N \) is large enough. On the contrary, it is also true that \( x_{\text{max}} \to 0 \) when \( N \to \infty \), suggesting that the maximally degenerated sector, and the one responsible for the behavior of the full Dicke Hamiltonian, is \( j = 0 \), or that corresponding to the lower value of \( j \) compatible with the given energy [25]. The solution of this apparent paradox is that \( g(N,x) \) becomes noncontinuous in the thermodynamical limit. Exact calculations from Eq. (19) show that

\[
g(N,0) = \frac{2 \Gamma(1+N)}{(2+N) \Gamma(1+N/2)^2},
\] (25)

\[
g(N,x_{\text{max}}) = \frac{N^{3/2} \Gamma(N)}{\Gamma\left(\frac{1-\sqrt{N}}{2}\right) \Gamma\left(\frac{1+\sqrt{N}+N}{2}\right)}.
\] (26)

And the corresponding asymptotic expansion when \( N \to \infty \) gives rise to

\[
g(N,0) \approx \frac{2^{3/2} 2^N}{\sqrt{\pi} N^{3/2}},
\] (27)

\[
g(N,x_{\text{max}}) \approx \frac{2^{3/2} e^{-1/2} 2^N}{\sqrt{\pi} N}.
\] (28)

Therefore, the degeneracy of the \( j_{\text{max}} \) sector is larger than the degeneracy of the sector with \( j = 0 \) for any finite-size system with \( N \) atoms, and the corresponding ratio is

\[
\frac{g(N,0)}{g(N,x_{\text{max}})} \approx \frac{e^{1/2}}{\sqrt{N}} \to 0, \text{ when } N \to \infty.
\] (29)
In other words, \( \lim_{N \to \infty} g(N, x_{\text{max}}) \neq g(N, 0) \) despite \( \lim_{N \to \infty} x_{\text{max}} = 0 \), implying that \( g(N, x) \) becomes non-continuous in the thermodynamical limit. Therefore, a rigorous calculation of the full density of states, \( \rho(E, N) \), and the corresponding expected values \( J_r(E, N) \) and \( J_r(E, N) \) requires us to take this fact into account. Notwithstanding, from a practical point of view this is only important if we are interested in finite-size systems, or in obtaining finite-size corrections to the behavior in the thermodynamical limit. A first-order approximation for the behavior in the thermodynamical limit can be obtained just by considering the lower \( j \) sector existing at a given energy \( E \), which coincides with \( j = 0 \) for \( E/N > 0 \) [25]. In the next sections we provide numerical results illustrating all these facts.

### B. Canonical ensemble

Let us consider that the system is in contact with a thermal bath, so the total Hamiltonian (system + environment) reads

\[
H = H_{\text{dike}} + H_{\text{bath}} + H_I, \tag{30}
\]

where \( H_I \) is the interacting term between the system (the Dicke model) and its environment. If we assume that \( \{H_I, J_2\} \neq 0 \) and \( \{H_I, \Pi\} \neq 0 \), we have to take into account both parities and all the possible values of the angular moments to derive the thermodynamics of the Dicke model. As it is indicated in Ref. [32], this is equivalent to a set of \( N \) fermions occupying either the lower or the upper level of a two-level system. Under such circumstances, the partition function can be explicitly obtained; this calculation was completed around 40 years ago [28]. Here, we summarize the main results.

The partition function can be exactly derived, giving rise to

\[
Z(N, \beta) = \frac{2^N}{\sqrt{\pi \beta \omega}} \int_{-\infty}^{\infty} dx \exp(-\beta \omega x^2) \left[ \cosh \left( \sqrt{\frac{N \omega_0^2 + 16 \lambda^2 x^2}{2N}} \right) \right]^N \tag{31}
\]

This integral cannot be solved in terms of simple analytical functions. Exact results have to be derived by means of numerical integration. The same procedure can be used to obtain the expected values of the relevant observables of the system. For example, we can obtain \( J_r \) and \( J_z \) considering

\[
J_r(N, \beta) = \frac{1}{Z(N, \beta)} \text{Tr}[J_r \exp(-\beta H)], \tag{32}
\]

where \( \alpha = x, y, z \) is a label. From this equation it is straightforward to obtain

\[
J_z(N, \beta) = -\frac{\omega_0 2^{N-1}}{Z(N, \beta)} \int_{-\infty}^{\infty} dx \exp(-\beta \omega x^2) \times \left[ \cosh \left( \sqrt{\frac{N \omega_0^2 + 16 \lambda^2 x^2}{2N}} \right) \right]^{N-1} \sinh \left( \sqrt{\frac{N \omega_0^2 + 16 \lambda^2 x^2}{2N}} \right) \left( \frac{\sqrt{N \omega_0^2 + 16 |\lambda|^2 x^2}}{\sqrt{N \omega_0^2 + 16 \lambda^2 x^2}} \right). \tag{33}
\]

Note that the last integral is an odd function in the \( x \) variable, so \( J_r(N, \beta) = 0 \). The same happens for any other symmetry-breaking observable, like, for example \( q = (a + a^\dagger)/2 \). Also, both \( E \) and \( J_r \) can be obtained directly from the partition function making use of Eqs. (11) and (12).

Since phase transitions are defined in the thermodynamic limit, \( N \to \infty \), we can apply Laplace’s method to evaluate the partition function. Defining \( y^2 = x^2/N \) we can write

\[
Z(N, \beta) = \frac{\sqrt{N}}{\sqrt{\pi \beta \omega}} \int_{-\infty}^{\infty} dy \exp \left\{ N \left[ -\beta \omega y^2 + \ln \left( 2 \cosh \left( \frac{\beta \omega_0}{2} \sqrt{1 + \frac{16 \lambda^2 y^2}{\omega_0^2}} \right) \right) \right] \right\}. \tag{35}
\]

As a consequence,

\[
\lim_{N \to \infty} Z(N, \beta) = \sqrt{\frac{2}{\beta |\Psi'(y_0)|}} \exp \{ N \Psi(y_0) \}, \tag{36}
\]

where

\[
\Psi(y) = -\beta \omega y^2 + \ln \left( 2 \cosh \left( \frac{\beta \omega_0}{2} \sqrt{1 + \frac{16 \lambda^2 y^2}{\omega_0^2}} \right) \right). \tag{37}
\]

and \( y_0 \) is the value of \( y \) which maximizes \( \Psi(y) \).

A phase transition normally happens when the position of the maximum \( y_0 \) changes at a certain critical temperature \( \beta_c \). The easiest way to obtain \( y_0 \) is solving \( \Psi'(y_0) = 0 \) and evaluating \( \Psi(y_0) \) for all the solutions. For the Dicke model, the trivial solution \( y_0 = 0 \) exists for all the temperatures and the values of the system parameters. Under certain circumstances, there also exists another solution,

\[
\frac{4 \lambda^2}{\omega} \tan \left( \frac{\beta \omega_0}{2} \sqrt{1 + \frac{16 \lambda^2 y_0^2}{\omega_0^2}} \right) = \omega_0 \sqrt{1 + \frac{16 \lambda^2 y_0^2}{\omega_0^2}}. \tag{38}
\]

Defining \( z = \sqrt{1 + 16 \lambda^2 y_0^2/\omega_0^2} \), the former equation reads

\[
\tanh \left( \frac{\beta \omega_0 z}{2} \right) = \omega_0 \sqrt{1 + \frac{16 \lambda^2 y_0^2}{\omega_0^2}}. \tag{39}
\]

It is important to note that, by definition, \( z > 1 \).

As \(-1 < \tanh(z) < 1 \) \( \forall z \), the former equation only has solutions if

\[
\lambda > \lambda_c = \sqrt{\frac{\omega_0 \omega}{2}}. \tag{40}
\]

Furthermore, the only way for Eq. (39) to have a solution for \( z > 1 \) is that \( \tanh \left( \frac{\beta \omega_0 z}{2} \right) > \frac{\omega_0}{2z} \) at \( z = 1 \); if this condition does not hold, the right-hand side of the equation is larger than the left for any \( z > 1 \). Therefore, if

\[
\beta < \frac{2}{\omega_0} \tanh^{-1} \left( \frac{\omega_0 \omega}{4 \lambda^2} \right). \tag{41}
\]
the only solution of the problem is the trivial one, \( y_0 = 0 \). On the contrary, if \( \beta \) exceeds this value, there exists a nontrivial solution \( y_0 \neq 0 \). Evaluating \( \Psi(0) \) and \( \Psi(\tilde{y}_0) \) we can see that \( \Psi(\tilde{y}_0) > \Psi(0) \) in all the cases. Therefore, the position of the maximum \( y_0 \) changes at the critical temperature

\[
\beta_c = \frac{2}{\omega_0} \tanh^{-1} \left( \frac{\omega_0 y_0}{4\lambda^2} \right).
\]

(42)

entailing that the partition function becomes nonanalytic at the critical temperature \( \beta_c \).

Summarizing, if \( \lambda < \lambda_c \), there is no thermal phase transition. At \( \lambda = \lambda_c \), the phase transition takes place at \( \beta \to \infty \), that is, at \( T \to 0 \); it constitutes a QPT. If \( \lambda > \lambda_c \), there exists a thermal phase transition at a critical temperature \( T_c = 1/\beta_c \). The values for \( \langle E \rangle \) and \( \langle J_e \rangle \) in the thermodynamical limit can be easily obtained by making use of Eqs. (11) and (12).

C. Spontaneous symmetry breaking at the critical temperature

Phase transitions are usually linked to the breakdown of a global symmetry of the Hamiltonian. Above the critical temperature, the stable phase has the same symmetries as the Hamiltonian; below, one of these symmetries becomes spontaneously broken. The main signature of this fact usually lies in the behavior of the order parameter. For example, the paradigmatic Ising model without external magnetic field is symmetric under the permutation of all the spins, but the system becomes spontaneously magnetized below the critical temperature. The usual order parameter of this transition reflects this fact. In any symmetric state, the total magnetization \( m = M/N \) is zero; however, \( m \) becomes different from zero in the ferromagnetic phase.

The seminal papers on the superradiant phase transition in the Dicke model do not consider this feature. As we have discussed above, the Dicke model has a discrete \( Z_2 \) symmetry, the parity \( \exp(\pi\{J + J_\parallel + a^\dagger a\}) \). The usual order parameters for the superradiant transition are either \( J_e \) or \( a^\dagger a \). These observables provide a good physical insight of the character of the transition: In the superradiant phase both the bosonic field and the upper level of the atomic system are macroscopically populated, even when \( \beta \to \infty \), giving rise to expected values \( \langle J_e \rangle \) and \( \langle a^\dagger a \rangle \) different from zero [27–29]. However, neither \( J_e \) nor \( a^\dagger a \) breaks the parity symmetry. Thus, it is interesting to seek alternative order parameters playing the same role as the magnetization in the Ising model. A good one is \( J_x \), which was recently used to study the ESQPT in the highly symmetric sector [21]. As \( \langle J_e \rangle = 0 \) in any eigenstate with well-defined parity, the strategy to study the behavior of this observable when crossing the phase transition consists in introducing a small symmetry-breaking term in the Hamiltonian,

\[
H_e = \omega a^\dagger a + \omega_0 J_x + \frac{2\lambda}{\sqrt{N}} J_x (a^\dagger a + a) + \epsilon J_x,
\]

(43)

and taking \( \epsilon \ll \omega, \omega_0, \lambda \).

The partition function of this system can be obtained following the same strategy as in the previous section. In the thermodynamical limit,

\[
\lim_{N \to \infty} Z_e(N, \beta) = \left[ \frac{2}{\beta |\Psi_e(y_0)|} \exp[N\Psi_e(y_0)] \right]^{1/2},
\]

(44)

where

\[
\Psi_e(y) = -\beta \omega y^2 + \ln \left( 2 \cosh \frac{\beta \omega_0 y}{2} \sqrt{1 + \frac{4\lambda y^2 + \omega_0^2}{\omega_0^2}} \right)
\]

(45)

and \( y_0 \) is the value that maximizes \( \Psi_e(y) \). From this result, we can obtain the expected values of \( J_x \) and \( J_e \) by means of

\[
\langle J_x \rangle_\epsilon = \frac{1}{\beta} \frac{\partial}{\partial \omega_0} \ln Z_e,
\]

(46)

\[
\langle J_e \rangle_\epsilon = \frac{1}{\beta} \frac{\partial}{\partial \epsilon} \ln Z_e.
\]

(47)

And finally, we can study both parameters in the limit \( \epsilon \to 0 \). It is worth remarking that this procedure entails that the thermodynamic limit is taken before the \( \epsilon \to 0 \) limit. Spontaneous symmetry breaking in phase transitions occurs because these limits do not commute, leading to a finite value of the symmetry-breaking order parameter even in the limit \( \epsilon \to 0 \).

In Fig. 4 we show the results for \( y_0 \), \( \langle J_x \rangle \), and \( \langle J_e \rangle \), both for the normal Dicke model and for the case with the symmetry-breaking term, considering the limit \( \epsilon \to 0 \) (see caption for details). We can see that including the symmetry-breaking term does not change the results for the critical temperature \( \beta_c \), the value of \( y_0 \), and the expected value for \( J_x \). However, \( \langle J_e \rangle \) changes dramatically: It is identically zero at both sides of the transition if the symmetry-breaking term is not included, but becomes different from zero in the superradiant phase if it is included, even if we take the \( \epsilon \to 0 \) limit. Hence, we conclude that the parity symmetry is spontaneously broken for \( \beta > \beta_c \), and that \( J_x \) is a good order parameter of the
transition. Furthermore, this observable plays the same role as the magnetization in the paradigmatic Ising model.

Summarizing, from the results shown in this section we conclude that \( J_x \) is the proper order parameter for the superradiant phase transition. In the following sections, we compare this finding and the recently published results about symmetry breaking and the ESQPT [21].

D. Numerical results: Different \( j \) sectors

Prior to studying the ESQPT and the thermal phase transition, we give a glimpse about the behavior of the different \( j \) sectors. In Fig. 5 we plot the results for the sectors \( j = 2N/16, 3N/16, \ldots, 8N/16 \), with \( \omega = \omega_0 = 1 \), \( \lambda = 1.5 \), and \( N = 1 \times 10^5 \). In particular, we deal with six different magnitudes: the density of states, \( \rho(E) \); the derivative of the density of states, \( \rho'(E) \); the third component of the angular momentum, \( \langle J_z \rangle \); the derivative of the third component of the angular momentum, \( \langle dJ_z/dE \rangle \); the temperature, \( \beta \); and the first component of the angular momentum, \( \langle J_x \rangle \). All these magnitudes are calculated by means of the microcanonical formalism; \( \beta \) is the microcanonical temperature

\[ \beta = \frac{\partial \ln \rho(E)}{\partial E}. \]  

We can see that the ESQPT occurs at a different energy for each different \( j \) sector. This is clearly seen in Figs. 5(b), 5(d), 5(e), and 5(f). The first three cases show logarithmic singularities associated with the derivatives of the density of states and the third component of the angular momentum [11]. It is worth mentioning that this singularity is also present in the microcanonical temperature \( \beta \). Also, note that \( \beta \) is not a monotonous function of the energy; this is a clear signature of the anomalous thermodynamic behavior of each \( j \) sector. Figure 5(f) shows the finite jump of the first component of
the angular momentum, provided that the initial state has the parity symmetry broken [21].

All these facts give important hints to understand the behavior of the full Hamiltonian, including all the $j$ sectors. If the system remains thermally isolated and follows a nontrivial time evolution, for example resulting from a time-dependent protocol $\lambda(t)$, both the total angular momentum, $J^2$, and the parity, $\Pi$, are conserved. This entails that the evolution of every $j - \Pi$ sector is totally independent of the others. The main consequences of this fact are the following: (i) every $j$ sector is affected by its ESQPT, showing the dynamical consequences reported in [10,21]; and (ii) the behavior of the total system is the sum of all the sectors, weighted by the corresponding degeneracies $g(N,\chi)$. In the next section we study the link between all these features and the thermal phase transition, well known since more than 40 years ago [28].

E. Numerical results: ESQPT versus thermal phase transition

In order to compare the physics of the isolated Dicke model (for which $J^2$ and $\Pi$ are conserved quantities) and the Dicke model in contact with a thermal bath (for which $J^2$ and $\Pi$ are not conserved), we proceed as follows. On the one hand, we obtain the microcanonical results, depending on the energy $E$, following the same procedure as in the previous section. On the other hand, the canonical calculation depends on $\beta$, and the energy is derived from Eq. (11). It predicts a critical temperature, given by Eq. (39), and hence we can obtain the corresponding values for the critical energy,

$$\langle E_c \rangle = -\frac{\partial \ln Z}{\partial \beta} \bigg|_{\beta_c},$$

the critical value of $J_z$,

$$\langle J_{z,c} \rangle = \frac{1}{\beta} \frac{\partial \ln Z}{\partial \omega_0} \bigg|_{\beta_c},$$

and the derivative of $J_z$,

$$\left\langle \frac{d J_{z,c}}{d E} \right\rangle = \frac{d}{d E} \left. \frac{1}{\beta} \frac{\partial \ln Z}{\partial \omega_0} \right|_{\beta_c} = \frac{d}{d \beta} \left. \frac{1}{\beta} \frac{\partial \ln Z}{\partial \beta} \right|_{\beta_c}. \quad (51)$$

With the values of the external parameters used in this work, $\omega = \omega_0 = 1$ and $\lambda = 1.5$, we obtain

$$\beta_c = 0.223144,$$

$$\langle E_c \rangle / N = -0.055,$$

$$\langle J_{z,c} \rangle = -0.055 = \langle E_c \rangle / N. \quad (54)$$

The derivative of $J_z$ is not defined at the critical temperature $\beta_c$; it jumps from zero to 1.

In Fig. 6 we plot the temperature $\beta$ in terms of the energy $\langle E \rangle / N$. We display the microcanonical result by means of a solid (green) line, and the canonical result by means of a dashed (red) line. The critical value for the energy is shown by a vertical dashed (blue) line, and the inset shows a zoom around the critical energy. Microcanonical calculation is done with $N = 1 \times 10^6$ particles. The canonical calculation is performed in the thermodynamical limit, by means of Laplace’s method. The results are pretty different from the ones obtained with the different $j$ sectors. First, we can see that $\beta$ is a monotonous function of the energy, as one expects from standard thermodynamics. Second, microcanonical and canonical ensembles give rise to the same results; in particular, both display the same critical behavior. However, we can also see an important difference. When the system is put in contact with a thermal bath, the region with $\langle E \rangle / N > 0$ is unreachable. In the canonical formalism, the limit $T \to \infty$ ($\beta \to 0$) corresponds with $\langle E \rangle / N \to 0$. Hence, if we heat the system by means of an external source of heat, we are restricted to the region with $\langle E \rangle / N < 0$. On the contrary, if the system remains isolated from any environment, and we heat the system by means of a mechanical procedure, for example performing fast cycles between $\lambda_i$ and $\lambda_f$, we can reach any final energy value. Note that $\langle E \rangle / N = 0$ acts like a second critical energy, since the curve $\beta(E)$ shows a singularity at this point.

Another remarkable fact is that the logarithmic singularities shown in Fig. 5(e) are washed out, despite results shown in Fig. 6 consisting of collecting all the $j$ sectors shown in Fig. 5(e), weighted by the corresponding degeneracy according to Eq. (19). On the other hand, the second singular point, taking place at $E_j^*/N = j/N$ in each $j$ sector, still occurs, at $E_j/N = 0$.

Results for the third component of the angular momentum, $J_z/N$, are shown in Fig. 7. We can see the same kind on nonanalyticity at the critical energy $E_c/N \sim -0.055$ as for the temperature $\beta$, despite the behavior for each $j$ sector, shown in Fig. 5(c), is totally different. Furthermore, both microcanonical and canonical calculations give the same results below $E_c/N = 0$. At this value, the microcanonical ensemble shows a second singular point, and $J_z/N = 0$ for $E/N > E_c/N$. It is worth remarking that, despite that the consequences of the ESQPT are not so clear for this magnitude, the minimum appearing in each $j$ sector just above the critical energy $E_j^*/N$ is not visible in the figure, giving rise to an approximately flat region $J_z/N \sim 0.055$ for $E < E_c$. However, a zoom around $E_c$ shows that this minimum still exists for finite systems (see below for more details).
The inset shows the same results around this critical value. Again, microcanonical and canonical ensembles give the same results, below $E_c/N = 0$. In this case, we can see a finite jump at the critical energy $E_c$; the logarithmic singularities, shown in Fig. 5(d), are also ruled out.

Finally, results for the first component of the angular momentum, $J_x/N$, are shown in Fig. 9. We depict the microcanonical result together with the calculation including the symmetry-breaking term, $\epsilon J_x$, described in Sec. IV C. Microcanonical calculations have been done considering that the parity symmetry is totally broken in the initial state, and therefore the integrals over the phase space are restricted to one of the two disjoint regions existing when $E_x/N < E_x/N$ in each $j$ sector. (If we perform the calculations on the other disjoint region, we obtain the same curve, but with negative values for $J_x/N$.) This observable shows a behavior that is qualitatively different than the previous ones. The main signature of the ESQPT is still present, but with a different qualitative behavior. $J_x$ is still an order parameter: it changes from $J_x \neq 0$ for $E < E_c$, to $J_x = 0$ for $E > E_c$. The main feature of the full Dicke model is that this change in continuous, despite that it is discontinuous in every $j$ sector experimenting on the ESQPT.

From all these results, we infer the following conclusions:

1) Microcanonical and canonical ensembles are equivalent below the singular point located at $E_c/N = 0$. This energy constitutes an unreachable limit if the system is put in contact with a thermal bath. It corresponds to $\beta \to 0$ (or $T \to \infty$). On the contrary, there is no such a limit if the system remains isolated.

2) The main signatures of the ESQPT are ruled out when we collect all the $j$ sectors: the logarithmic singularities in the derivatives of $\rho$ and $J_z$ are present neither when the system is isolated (microcanonical calculation) nor when it is in contact with a thermal bath (canonical calculation). As these singularities are linked to stationary points in the corresponding semiclassical phase space, we can conclude that the relevance of such classical structures vanishes when all the $j$ sectors are taken into account. A possible explanation, compatible with Ref. [24], is that, in this case, the number of effective degrees of freedom becomes infinite, since we have an infinite number of $j$ sectors (each one with $f = 2$ degrees of freedom) in the thermodynamical limit.

3) Contrary to what happens with the other main signatures of the ESQPT, the breakdown of the $Z_2$ parity symmetry below the critical energy (or temperature) survives. If the system remains isolated from any environment, the system behaves as follows. Below the critical energy, $E < E_c$, the parity symmetry remains broken if it is broken in the initial condition; on the contrary, time evolution above the critical energy $E > E_c$ restores the symmetry [21,22]. This entails that the expected value $\langle J_z \rangle$ keeps relevant information about the initial state. On the other hand, parity symmetry becomes spontaneously broken if the system is in contact with a thermal bath, as discussed in Sec. IV C. The most significant result shown in Fig. 9 is that this breakdown exactly coincides with the microcanonical result, when the integration over the phase space is restricted to one of the two disjoint regions existing for $E < E_c$. That is, thermal fluctuations make the system spontaneously choose one of these two possibilities.
from the analytical results to study the finite-size scaling of
be exactly solved by numerical diagonalization, and to profit
test the applicability of our results to systems small enough to
evaluate the partition function. On the contrary, this limit
thermodynamical limit, relying on the Laplace method to
obtained following different strategies. When the system is
in contact with a thermal bath, that is, when we work in
microcanonical integrals have been performed
without including
both with the parity symmetry totally broken, \((\Pi) = 0\). Hence, to
collect the results for all the \(j\) sectors, we have done
two different histograms, one including all the levels with
\(\langle J_\epsilon \rangle > 0\) and the other including the levels with
\(\langle J_\epsilon \rangle < 0\). Also, two microcanonical integrals, Eq. (22), are
performed, each one restricted to the corresponding disjoint region of
the energy surface. It is worth remarking that the micro-
canonical integrals have been performed without including
the symmetry-breaking term. Above the critical energy, only
one integration region is considered, since the energy surface
is not split anymore. In this phase, the spectrum consists of
doublets, one level with \(\langle J_\epsilon \rangle > 0\) and another with \(\langle J_\epsilon \rangle < 0\),
both with the parity symmetry totally broken, \((\Pi) = 0\). Hence, to
collect the results for all the \(j\) sectors, we have done
two different histograms, one including all the levels with
\(\langle J_\epsilon \rangle > 0\) and the other including the levels with
\(\langle J_\epsilon \rangle < 0\). Also, two microcanonical integrals, Eq. (22), are
performed, each one restricted to the corresponding disjoint region of
the energy surface. It is worth remarking that the micro-
canonical integrals have been performed without including
the symmetry-breaking term. Above the critical energy, only
one integration region is considered, since the energy surface
is not split anymore. In this region, the numerical calculations
show that every eigenstate has well-defined parity, despite the
small symmetry-breaking term introduced in the Hamiltonian,
and that the expected value of \(J_\epsilon\) is always zero. All these
facts are visible in Fig. 11. The match between numerical
and microcanonical results is very good, except in the very
surroundings of the critical energy. As large finite-size effects
for this observable have been observed in the highly symmetric
sector \([21]\), the small discrepancies observed in the figure are
not surprising.
We can profit from the previous results to perform a finite-
size scaling analysis of the transition. In particular, we rely on

\caption{Exact numerical results (solid red circles) and micro-
canonical calculation (solid green curves) for the expected value of
\(J_\epsilon/N\), in a system with \(N = 50\) atoms. Numerical results have been
obtained after introducing a small symmetry-breaking term, \(\epsilon J_\epsilon\), with
\(\epsilon = 1 \times 10^{-6}\). For the analytical result, the symmetry-breaking term
is not introduced, and the two disjoint regions of the phase space
below the critical energy are integrated separately, to obtain the two
branches of the theoretical curve.}
\end{figure}

Hence, it is very worth noting the similarity in the behavior of
\(\langle J_\lambda \rangle\) in both the excited-state and the thermal quantum phase
transitions, though the behavior of the system is not the same
in isolation as it is in contact with a thermal bath.

\section{F. Results: Finite-size scaling}
Numerical results in the previous section have been obtained
following different strategies. When the system is
in contact with a thermal bath, that is, when we work in
the canonical ensemble, we make the calculations in the
thermodynamical limit, relying on the Laplace method to
evaluate the partition function. On the contrary, this limit
is not explicitly done when the system is in isolation and
the microcanonical ensemble is considered. Furthermore,
our method is applicable to finite-size systems, at least if they are
large enough to apply the semiclassical approximation to each
\(j\) sector, and to consider that \(\lambda = j/N\) is very approximately
a continuous variable \(\lambda \in [0,1/2]\). The aim of this section is to
test the applicability of our results to systems small enough to
be exactly solved by numerical diagonalization, and to profit
from the analytical results to study the finite-size scaling of
the critical behavior.

In Fig. 10 we plot the numerical results for \(\langle J_\lambda \rangle\) obtained
with a system with \(N = 50\) atoms including all the \(j\) sectors,
together with the microcanonical prediction given by Eq. (21).
Numerical results have been obtained as follows. The Hamilto-
nian of each \(j\) sector, \(H_j\), is independently diagonalized. Then,
the expected value in each eigenstate, \(J_\lambda(n,j) = \langle E^n_j \mid J_\lambda \mid E^n_j \rangle\),
is calculated. Finally, results for all the \(j\) sectors are collected in
a histogram with bins of size \(\Delta E/N = 0.05\), after considering
the degeneracy of each sector, \(g(N,j)\). As the actual number
of photons is unbounded, the dimension of the Hilbert space
is infinite, and hence the diagonalization procedure requires a
truncation in the photonic Hilbert space. For all the calculations
shown in this section, we have taken \(n_{\text{max}} = 500\) photons, a
number large enough to ensure convergence in our results.

The match between theory and numerics is remarkable,
taking into account all the approximations required to obtain
the microcanonical result. At low energies, we see a kind
of sawtooth structure in the numerical results, which is a
consequence of the integrable nature of the low-lying spectrum
of the Dicke model [36]. Besides this fact, the microcanonical
results give a perfect description of the model. It is worth
remarking on the presence of a small dip close to the critical
energy of the ESQPT. As it is discussed below, this dip is a
remnant of the ESQPT and vanishes in the thermodynamical
limit.

In Fig. 11 we plot the results for \(J_\epsilon\), obtained by means of
a procedure similar to the previous one. In this case, a small symmetry-breaking term, \(\epsilon J_\epsilon\), with \(\epsilon = 1 \times 10^{-6}\),
has been introduced for the numerical diagonalization. As a
consequence, the (almost) exact degeneracy of energy levels
below \(E_c\) is broken; in this phase, the spectrum consists of
doublets, one level with \(\langle J_\epsilon \rangle > 0\) and another with \(\langle J_\epsilon \rangle < 0\),
both with the parity symmetry totally broken, \((\Pi) = 0\). Hence, to
collect the results for all the \(j\) sectors, we have done
two different histograms, one including all the levels with
\(\langle J_\epsilon \rangle > 0\) and the other including the levels with
\(\langle J_\epsilon \rangle < 0\). Also, two microcanonical integrals, Eq. (22), are
performed, each one restricted to the corresponding disjoint region of
the energy surface. It is worth remarking that the micro-
canonical integrals have been performed without including
the symmetry-breaking term. Above the critical energy, only
one integration region is considered, since the energy surface
is not split anymore. In this region, the numerical calculations
show that every eigenstate has well-defined parity, despite the
small symmetry-breaking term introduced in the Hamiltonian,
and that the expected value of \(J_\epsilon\) is always zero. All these
facts are visible in Fig. 11. The match between numerical
and microcanonical results is very good, except in the very
surroundings of the critical energy. As large finite-size effects
for this observable have been observed in the highly symmetric
sector \([21]\), the small discrepancies observed in the figure are
not surprising.

We can profit from the previous results to perform a finite-
size scaling analysis of the transition. In particular, we rely on
the theoretical expressions for the microcanonical ensemble to study how the statistical results depend on the system size $N$. Results for the finite-size precursor of the critical energy $E_c^{(N)}$ are shown in Fig. 12. We plot the difference between this precursor and the critical energy obtained by means of the canonical calculation, $E_c^{(N)} - E_c$ versus the size of the system, in a double logarithmic scale. We also show a straight line representing the power-law behavior $E_c^{(N)} - E_c \propto N^{-\alpha}$, with $\alpha(J_z) \sim 0.47$ and $\alpha(J_x) \sim 0.41$. Calculations have been performed as follows. In the left panel, $E_c^{(N)}$ is estimated as the energy corresponding to the minimum of $J_z/N$. Though not explicitly shown, this minimum becomes less pronounced as the system size grows, vanishing in the thermodynamical limit. In the right panel, $E_c^{(N)}$ is identified as the energy at which $J_z/N$ becomes less than 0.01. This bound is arbitrary, but we are not interested in quantitative results for each system size $N$, but in their scaling with the system size. From the results shown in Fig. 12, we can conclude that the finite-size precursor $E_c^{(N)}$ tends to the critical energy $E_c$, with a power-law finite-size scaling.

In Fig. 13 we show the same results for the critical value of the third component of the angular momentum, $J_{z,c}^{(N)} - J_{z,c}$. Though in this case the scaling is not so clean, we still can conclude that $J_{z,c}^{(N)} - J_{z,c} \propto N^{-\alpha}$, with $\alpha \sim 0.40$.

V. CONCLUSIONS

In this work we have analyzed the relationship between the thermal phase transition and the ESQPT in the Dicke model. First of all, we have studied the thermodynamics of the model by means of microcanonical and canonical ensembles, and we have found that both approaches are incompatible if we consider just the highly symmetric representation, i.e., $j = N/2$. The reason is that the size of the Hilbert space grows linearly with the number of atoms, $N$, instead of exponentially. The main consequence is that extensive thermodynamic magnitudes, like the entropy $S$ or the Helmholtz potential $F$, do not scale with the number of particles, $N$; thermodynamics is anomalous and the different ensembles are not equivalent in the thermodynamic limit, $N \to \infty$. In order to get a correct description of the thermodynamics properties it is necessary to include all the $j$ sectors.

To perform the microcanonical calculation including all the $j$ sectors, we have considered that all them can be adequately described by means of the semiclassical approximation. As a consequence, the results for the complete Hilbert space can be written as an integral collecting all the sectors, provided that the number of particles is large enough. We have shown that $N \geq 50$ atoms are enough to guarantee the goodness of this approximation.

We have shown that each $j$ sector is equivalent to the one with $j = N/2$, but with a smaller effective coupling strength. The main consequence is that, despite all of them having an ESQPT if the global coupling strength $\lambda$ is large enough, for any finite value $\lambda > \lambda_c$ there are a large number of $j$ sectors which are in the normal phase. To illustrate this fact, we have computed different magnitudes for different $j$ values: the density of states, $\rho(E)$; the derivative of the density of states, $\rho'(E)$; the third component of the angular momentum, $\langle J_z \rangle$; the derivative of the third component of the angular momentum, $\langle d J_z / d E \rangle$; the temperature $\beta$; and the first component of the angular momentum, $\langle J_1 \rangle$.

We have analyzed the relationship between ESQPT and thermal phase transition when all the $j$ sectors are taken into account. This fact entails that the main signatures of the ESQPT, in particular the logarithmic singularities in the derivatives of the density of states and the expected value of $J_z$, are ruled out. However, $\langle J_z \rangle$ still changes from a value different from zero below the critical energy or the critical temperature, to zero above them. In particular, we have shown that the parity...
symmetry is spontaneously broken in the thermodynamical limit if the system is in contact with a thermal bath (and thus, the canonical ensemble is used). Results obtained in this way coincide with the microcanonical calculations, if the integration in the phase space is restricted to one of the two disjoint regions existing when $E < E_{c}$. Parity symmetry becomes spontaneously broken at temperatures (or energies) at which the underlying semiclassical space is split into two regions; thermal fluctuations make the system choose one of the two existing disjoint regions.

Finally, we have also discussed the main physical differences between the Dicke model in isolation and in contact with a thermal bath. Despite that both the microcanonical and canonical descriptions mainly coincide in the thermodynamic limit, one important difference remains. If the system is in contact with a thermal bath, that is, if it is described by means of the canonical ensemble, the energy $E_{c}/N = 0$ constitutes an upper bound; this energy implies $T \rightarrow \infty$, and thus cannot be exceeded in any experiment. On the contrary, if the system remains thermally isolated and is heated by means of the Joule effect, for example by quenching $\lambda_{i} \rightarrow \lambda_{j} \rightarrow \lambda_{l}$ repeatedly, the limit $E_{c}/N = 0$ can be exceeded; in other words, $E/N > 0$ are accessible in the microcanonical description.
