Abstract

The Variscan suture exposed in NW Iberia contains a stack of terranes including two allochthonous units with continental affinity and Gondwanan provenance (Upper and Basal Units), separated by an ophiolite belt where the most common units show protolith ages at c. 395 Ma. Recent Lu–Hf zircon data obtained from these ophiolites indicate interaction between the gabbroic magmas and old continental crust. Hence, the ophiolites could not have originated in a deep ocean basin associated with a mature mid-ocean-ridge or intraoceanic subduction. The tectonothermal evolution of the continental terranes bounding the suture zone records two consecutive events of deep subduction. The Upper Units record an initial high-P/ultra-high-P metamorphic event that occurred before 400–390 Ma, while the Basal Units were affected by a second high-P/low-to-intermediate-T metamorphic event dated at c. 370 Ma. Continental subduction affected the most external margin of Gondwana and developed in a setting of dextral convergence with Laurussia. Development of the two high-P events alternated with the opening of an ephemeral oceanic basin, probably of pull-apart type, in Early Devonian times. This ephemeral oceanic domain is suggested as the setting for the protoliths of the most common ophiolites involved in the Variscan suture. Current ideas for the assembly of Pangea advocate a single collisional event between Gondwana and Laurussia in the Carboniferous. However, the new evidence from the allochthonous terranes of the Variscan belt suggests a more complex scenario for the assembly of the supercontinent, with an interaction between the colliding continental margins that started earlier and lasted longer than previously considered. Based on modern analogs of continental interaction, the development of complex collisions, as here suggested for Gondwana and Laurussia during the assembly of Pangea, could have been the norm rather than the exception throughout Earth history.

Keywords: Assembly of Pangea, Allochthonous, Variscan terranes, NW Iberian Massif

1. Introduction

It is broadly accepted that the assembly of Pangea occurred in Carboniferous and Early Permian times, after a long stage of continental convergence that ended with the closure of the Rheic Ocean (e.g. Nance et al., 2010 and references therein) and the collision of Gondwana and Laurussia (Stamfli and Borel, 2002; Murphy and Nance, 2008). This collision resulted in the formation of the Variscan–Appalachian–Alleghanian orogen, which extends from Europe to eastern North America and contains key information for reconstructing the amalgamation history of the supercontinent. In the Variscan belt, the oldest tectonothermal events are preserved in a complex suture zone that can be traced from the Iberian Peninsula to the Bohemian Massif (Fig. 1).

This belt is affected by several oroclinal folds, but the original geometry was broadly linear (Matte, 2001; Martínez Catalán, 2011; Weil et al., 2012). The suture zone is made up of a stack of allochthonous terranes with ophiolites and high-P (HP) and ultra-high-P (UHP) metamorphic rocks. One of the most distinctive features of the Variscan belt is the presence of two different events of HP metamorphism that appear to have occurred relatively close in time, but were separated by the development of oceanic basins. This evolution is unusual in large collisional belts, whose tectonothermal evolution is commonly interpreted as reflecting a single HP or UHP metamorphic event associated with subduction of one of the colliding continental margins (Platt, 1986; Beaumont et al., 2009). In the Variscan belt, both HP events and the development of some of the oceanic domains occurred after the earliest Devonian and are thus broadly coeval with the initial stages of the assembly of Pangea. This paper presents a short summary of the origin and tectonothermal evolution of the allochthonous terranes involved in the Variscan suture, and proposes a conceptual model to integrate part of this history in the context of Pangea formation. The geological section exposed in the NW Iberian Massif is taken as an example and described in some detail, but
allochthonous terranes are fairly continuous along the suture and largely comparable throughout the European Variscan belt (Faryad and Kachlík, 2013; Kroner and Romer, 2013). Recent isotopic and geochronologic data on the origin of the Ophiolitic Units and U–Pb geochronological constraints on the HP events provide new insights into the early events involved in the formation of Pangea. The history of convergence and collision is probably longer and more complex than previously described.

2. Terranes involved in the Variscan suture

The NW Iberian section of the Variscan belt contains different terranes with contrasting origins and tectono-thermal evolution (Arenas et al., 1986; Martínez Catalán et al., 2009). The Central Iberian Zone represents the lowest sequence and together with a parautochthonous domain (or Schistose Domain) defines the main section of the Gondwanan margin involved in the Variscan orogen (Martínez Catalán et al., 2009) (Figs. 1 and 2). On top, a set of allochthonous terranes of alleged exotic nature forms a nappe stack representative of the suture zone (Figs. 1 and 2). Three main groups of terranes have been identified, two of which show continental affinities (Basal and Upper Units). These are separated by ophiolites representing the suture itself (Ophiolitic Units, Fig. 2).

Located immediately below the suture, the Basal Units contain metasedimentary rocks (comprising a thick pile of metagreywackes with minor metapelites, graphitic schist, calc-silicate lenses, metacherts and quartzites), calc-alkaline to alkaline–peralkaline metagranitoids, and some mafic rocks. Maximum depositional ages for the metasedimentary series range between Ediacaran and Early Ordovician (Diez Fernández et al., 2010, 2013), with Nd model ages between 1.78 and 2.22 Ga (Fuenlabrada et al., 2012). Major and trace element geochemistry of the metagreywackes suggest deposition in association with a peri-Gondwanan arc system built upon a thinned continental margin. The calc-alkaline (c. 493 Ma; Abati et al., 2010) and alkaline–peralkaline (c. 475–470 Ma; Diez Fernández et al., 2012a) granitoids were generated within this arc, suggesting an evolution from convergence to continental rifting. The Basal Units are considered to represent a section of the most external margin of Gondwana located somewhere between the West African and Saharan cratons (Diez Fernández et al., 2010). The first tectono-thermal event recorded in these units is a HP and low- to intermediate-T (LIT) event dated at c. 370 Ma (Rodríguez et al., 2003; Abati et al., 2010). A variety of HP mica schists and orthogneisses, C-type eclogites and some blueschists were formed at this time (Arenas et al., 1995, 1997; Rodríguez et al., 2003; López Carmona et al., 2013).

Resting on top of the suture zone, the Upper Units consist of a pile, 10–12 km thick, of metasedimentary rocks (mainly metagreywackes), large massifs of calc-alkaline orthogneisses, and gabbros with compositions of island-arc tholeiites, together with medium to high grade mafic rocks, including B-type eclogites (Coleman et al., 1965) and HP granulites, and some ultramafic massifs. The low grade metagreywackes located in the uppermost position have a Middle Cambrian maximum depositional age (Fernández-Suárez et al., 2003), with Nd model ages ranging between 0.72 and 1.22 Ga, and major and trace element compositions typical of active margin settings (Fuenlabrada et al., 2010). Protolith ages for gabbros and granitoids range between 490 and 520 Ma (Fernández-Suárez et al., 2007; Andonaegui et al., 2012). These units were part of a Cambrian peri-Gondwanan magmatic arc, and were located west of the external margin section represented by
the Basal Units (Díez Fernández et al., 2010; Fuenlabrada et al., 2010). The Upper Units may be divided into two groups according to metamorphic criteria: an uppermost section with intermediate-P metamorphism ranging from the chlorite zone to the granulite facies, and a lower section showing HP and HT metamorphism dated at c. 400–390 Ma (Ordóñez Casado et al., 2001; Fernández-Suárez et al., 2007). The latter metamorphic event reached UHP conditions in other domains of the Variscan belt (Lardeaux et al., 2001). The main tectonothermal events recorded in the uppermost section are Cambrian in age and were probably developed in response to the accretionary dynamics of the peri-Gondwanan arc system (Abati et al., 1999, 2007; Díaz García et al., 2010).
The ophiolites of NW Iberia have received considerable attention in the past few years with papers describing in detail their lithologies, chemical compositions and isotopic geochronology. It is now well-established that their igneous protoliths range quite widely in age, thereby precluding their generation within a single oceanic domain. Two groups of Ophiolitic Units have been distinguished (Fig. 2): an older group (Lower Ophiolitic Units) containing metagneissic rocks of Late Cambrian age (c. 497–495 Ma), and a younger group (Upper Ophiolitic Units) including gabbroic rocks of Devonian age (Emsian–Eifelian; c. 395 Ma).

The Cambrian ophiolites comprise either thick sequences of green-schists (with island-arc tholeiite compositions), with some later tonalitic orthogneisses (Vila de Cruces Ophiolite; Arenas et al., 2007a; Fig. 2), or c. 4000 m of HT metagabbroic amphibolites with N-MORB affinities and minor ultramafic rocks (Bazar Ophiolite; Sánchez Martínez et al., 2012; Fig. 2). The protoliths of the Vila de Cruces Ophiolite were formed during the opening of a back-arc basin at the periphery of Gondwana. In contrast, based on its chemical composition and structural position, the Bazar Ophiolite probably represents a relic of the Cambrian peri-Gondwanan Iapetus-Tornquist Ocean, accreted below a system of peri-Gondwanan volcanic arcs. This accretion is dated at c. 475 Ma based on U–Pb zircon geochronology for the timing of the HT metamorphism affecting the mafic protoliths. The Lower Ophiolitic Units are interpreted to represent a series of mafic complexes linked to the dynamics affecting the most external margin of Gondwana in Cambrian–Early Ordovician times.

The Middle Devonian ophiolites are the most abundant group found in the Variscan suture (Murphy et al., 2011). In addition to NW Iberia, they occur in the Lizard Complex (Lizard Ophiolite; Clark et al., 1998; Nutman et al., 2001), in the Armorican Massif (Drain Ophiolite; Ballèvre et al., 2009, 2012), and in the Bohemian Massif (Ślęża ińska Ophiolite; Dubitska et al., 2004; Kryza and Pin, 2010). In Galicia (NW Spain), the Careón Ophiolite (395 ± 2 Ma, U–Pb zircon in metagabbro; Díaz García et al., 1999; Pin et al., 2002; Fig. 2) has received special attention and can be considered the type example of the group. It is made up of three imbricate slices, the thickest (c. 1000 m) of which contains a sequence of peridotites overlain by 500 m of isotropic gabbros. Both the peridotites and the gabbros are intruded by stocks of pegmatitic gabbros and numerous doleritic dykes. The ophiolite contains no sheeted dyke complex and no volcanic or sedimentary rocks, at variance with common N-MORB oceanic ophiolites. The protoliths of the Vila de Cruces Ophiolite were formed during the opening of a back-arc basin at the periphery of Gondwana. In contrast, based on its chemical composition and structural position, the Bazar Ophiolite probably represents a relic of the Cambrian peri-Gondwanan Iapetus-Tornquist Ocean, accreted below a system of peri-Gondwanan volcanic arcs. This accretion is dated at c. 475 Ma based on U–Pb zircon geochronology for the timing of the HT metamorphism affecting the mafic protoliths. The Lower Ophiolitic Units are interpreted to represent a series of mafic complexes linked to the dynamics affecting the most external margin of Gondwana in Cambrian–Early Ordovician times.

The Upper Units have been previously interpreted as a section of a peri-Gondwanan volcanic arc that rifted off the continental margin in Cambrian–Early Ordovician times and drifted northward, opening the Rheic Ocean in its wake. This riftting would have coincided with the rift and drift of the Avalonian microcontinent. The Upper Units, however, would have had a different identity and provenance since they were located further to the east along the paleo-margin of Gondwana (Abati et al., 2007; Gómez Barreiro et al., 2007; Díez Fernández et al., 2010). The HP or UHP metamorphic event that affected the lower section of the Upper Units at c. 400–390 Ma would have been generated during the accretion of this terrane to the southern margin of Laurussia, this process highlighting the switch from a divergent to a convergent setting in the evolution of the Rheic Ocean. The geodynamic evolution hinted at for the Upper Units implies that the ophiolites involved in the Variscan suture were developed in the realm of the Rheic Ocean. The Cambrian ophiolites — with the exception of the Bazar Ophiolite — would be related to early stages in the opening of this ocean, while the Devonian ophiolites would have been formed during the final stages of its closure (Arenas et al., 2007b).

For this reason, it has been proposed that the Devonian ophiolites were formed in a northward dipping intra-Rheic Ocean supra-subduction zone located close to the southern margin of Laurussia (Díaz García et al., 1999; Sánchez Martínez et al., 2007). Such intraoceanic subduction zone would have generated buoyant oceanic lithosphere that would have readily accreted beneath Laurussia and eventually been obducted over the external margin of Gondwana (Basal Units) at the beginning of the Variscan deformation (c. 370 Ma). Furthermore, the activity of this intraoceanic subduction zone would have consumed a significant tract of the Rheic Ocean, thus explaining the general absence of typical N-MORB lithosphere in the Variscan suture.

However, the aforementioned models link the generation of the Devonian ophiolites to an open-ocean setting incompatible with the new isotopic data that clearly show the interaction of the gabbroic protoliths with old continental crust. Many of the zircons analyzed in mafic rocks from the Purrido and Moeche ophiolites show Lu–Hf isotopic compositions only compatible with a continental origin. These zircons can be only interpreted as inherited crystals incorporated into the mafic magmas (Sánchez Martínez et al., 2011; Arenas et al., in press). Consequently, there is no conclusive evidence to link the generation of the Devonian ophiolites either to the evolution of the Rheic Ocean or to an intraoceanic subduction zone active in a mature ocean basin. If the connection between the Variscan suture of NW Iberia and the evolution of the Rheic Ocean is called into question, so must the interpretation of the Upper Units as a peri-Gondwanan terrane that drifted away during the opening of this Paleozoic ocean. Moreover, problems also exist in attributing the development of HP–UHP meta-morphism in the trailing edge of a rather small terrane to its collision with Laurussia. The tectonothermal evolution expected for the accretion of a small, ribbon terrane to a large continent would be one more compatible with soft collision, without generation of important subduction and, hence, lacking HP–UHP metamorphism. In contrast, the latter is usually associated with deep subduction of the thinned margin of a large continent during its collision with another large continent (Warren et al., 2008; Beaumont et al., 2009).

It is also noteworthy that the age of the HP–UHP metamorphic event in the Upper Units, which is constrained to be no younger than 400–390 Ma (U–Pb zircon; Ordóñez Casado et al., 2001; Fernández-Suárez et al., 2007), is similar to that of the mafic rocks of the Upper Ophiolitic Units, repeatedly dated at c. 400–395 Ma (U–Pb zircon; Díaz García et al., 1999; Pin et al., 2002, 2006; Sánchez Martínez et al., 2011; Arenas et al., in press). In the case of the HP metamorphic event, the U–Pb geochronology provides the age of the HT zircon growth, which occurred sometime after the continental margin became involved in the subduction system. Accordingly, the peak pressure of the HP event must have been reached prior to 400–390 Ma since this age likely marks a point along the exhumation/decompression path (Fernández-Suárez et al., 2007). This subduction must also predate the generation of the Devonian mafic rocks, as expressed in recent papers focused on the origin of the allochthonous terranes of NW Iberia (Sánchez Martínez et al., 2007; Martínez Catalán et al., 2009).
Hence, the new data from the allochthonous terranes of NW Iberia, in particular Lu–Hf isotope geochemistry of the Devonian ophiolites and detailed U–Pb geochronology of the two HP metamorphic events, seem to be more consistent with the development of two successive collision events between Gondwana and Laurussia, each taking place in a context of oblique convergence and separated in time by the opening of a rather wide oceanic basin, probably of pull-apart type.

The allochthonous Upper Units are herein interpreted as the most external part of the Gondwanan margin, a rather wide continental shelf containing thick turbidite series intruded by large massifs of gabbros and granitoids. This lithological succession was formed during the activity of a volcanic arc in Cambrian times, having developed after an important episode of crustal extension and thinning. This continental shelf did not witness significant new igneous activity or deformation until the onset of the HP–UHP metamorphic event, and hence shows the characteristics of a typical passive margin for most of the Ordovician and Silurian. In the geological record covering this time interval there is no evidence suggesting any significant separation of this continental shelf from the Gondwanan mainland. Convergence between Gondwana and Laurussia led to a first continental collision before 400–390 Ma, including the dextral subduction (Ábalos et al., 2003) of the most external and thinned part of the Gondwanan margin to the north accompanied by the first HP–UHP metamorphism. The southern margin of Laurussia acted as the upper plate in the subduction complex and the most important collision probably affected the eastern part of Avalonia and the Baltic margin (Fig. 3).

Renewed dextral motion between Gondwana and Laurussia favored the rapid generation of a rather wide pull-apart basin in Early Devonian times, which we interpret as the tectonic setting for the generation of the c. 395 Ma mafic rocks forming the most typical ophiolites involved in the Variscan suture (Fig. 4). The pull-apart basin currently being generated between the North American Plate and the Caribbean Plate can be considered a modern analog for the suggested tectonic setting, although in this case the lateral component is sinistral. The Gonâve microplate occupies the pull-apart basin and comprises oceanic lithosphere with a rather thin or completely absent sedimentary cover (ten Brink et al., 2002). This oceanic lithosphere is being generated by the activity of the Mid-Cayman Spreading Centre (Fig. 5). In this modern analog, as was probably the case at the beginning of Pangaea assembly, the pull-apart basin was generated following an initial collision that produced the high-P belts in northern Cuba and Hispaniola (Fig. 5) (García-Casco et al., 2008; Sommer et al., 2011).

Continued dextral convergence finally caused the closure of the pull-apart basin and the accretion of buoyant oceanic lithosphere beneath the northern continent starting at c. 380 Ma (Careón and Parrido ophiolites; Dallmeyer et al., 1997). The accreted oceanic lithosphere is mostly metamorphosed to the amphibolite facies, but the occasional presence of corundum-bearing metamorphic sole indicates the local- ized presence of high thermal gradients (Díaz García et al., 1999). Later accretion of new Devonian mafic slices took place under greenschist facies conditions (Moeche Ophiolite), and was followed by the accretion of mafic complexes rimming the continental margin that formed within the Cambrian peri-Gondwanan volcanic arc (Vila de Cruces Ophiolite). The final outcome was the generation of a complex suture zone that records protracted dextral convergence and is characterized by the presence of a double ophiolitic belt of contrasting origin.

---

Fig. 3. Reconstructions of (a) the Rheic Ocean realm at the Silurian — Devonian boundary, and (b) the initial collision between Gondwana and Laurussia at c. 410–400 Ma, following the complete closure of the Rheic Ocean. This collision caused subduction of the most external margin of Gondwana and generated the HP–UHP metamorphic belt preserved in the allochthonous Upper Units exposed in the Variscan suture. The true Rheic Ocean suture is not represented in the mapped area of NW Iberia.

---

Fig. 4. Reconstructions showing (a) dextral motion between Gondwana and Laurussia, which favored the opening of a rather ephemeral pull-apart basin at c. 395 Ma with generation of new oceanic lithosphere, and (b) the second and final collision at c. 380–370 Ma, which caused the accretion of buoyant oceanic lithosphere followed by new subduction affecting the margin of Gondwana, thereby developing a second HP–LHT metamorphic belt. The two different HP belts and the ophiolitic units dated at c. 395 Ma can be identified in the allochthonous terranes that outline the Variscan suture from Iberia to the Bohemian Massif.
and ages: the Upper Ophiolitic Units of Devonian age and the Lower Ophiolitic Units of Cambrian age. The occurrence of a thick serpentinite mélange at the base of the allochthonous pile was interpreted in the context of dextral convergence (Somozas mélange, Fig. 2; Arenas et al., 2009).

The final collision between Gondwana and Laurussia started at c. 370 Ma as a consequence of continued oblique dextral convergence (Díez Fernández et al., 2012b). It caused renewed north-directed subduction affecting a new section of the external Gondwanan margin with a more easterly provenance (in Gondwanan margin coordinates; Basal Units; Díez Fernández et al., 2010; Fuenlabrada et al., 2012). This is the suggested setting for the development of the second HP metamorphic event, formed under LIT conditions and generating C-type eclogites (Coleman et al., 1965), blueschists and HP metapelites (Fig. 4). Convergence continued for about 70 m.y. (Dallmeyer et al., 1997) as intracontinental deformation progressed southward, reaching inner sections of Gondwana while building a foreland fold and thrust belt in the external parts of the orogen.

4. Conclusions

Previous interpretations for the final assembly of Pangea call upon a single-stage collision between Gondwana and Laurussia in Carboniferous times. However, recent data regarding the origin and tectothermal evolution of the allochthonous terranes involved in the Variscan suture suggest a more complex and longer history for the early stages in the assembly of the supercontinent. These data are consistent with two successive collisional events separated by the generation of a relatively ephemeral oceanic basin. The first collision occurred in Early Devonian times (before c. 400-390 Ma) and caused deep subduction of the most external margin of Gondwana and the generation of a HP-UHP metamorphic belt (Upper Units of the Variscan suture). Continued dextral motion between Gondwana and Laurussia favored the opening of a relatively large pull-apart basin at c. 400-395 Ma. The rapid closure of this basin started at c. 380 Ma and caused the accretion of buoyant oceanic lithosphere of Devonian age below the northern continent. This oceanic lithosphere is represented by the most common ophiolites found in the European Variscan suture (Upper Ophiolitic Units). Mafic slices with a similar age and showing greenschist facies recrystallization were accreted later, followed by mafic complexes with Cambrian age generated by the activity of peri-Gondwanan volcanic arcs that progressively reached the collision zone as the basin shrank (Lower Ophiolitic Units). Finally, renewed dextral convergence led to a new collision with another section of the Gondwanan margin at c. 370 Ma and the generation of a second HP-LIT belt (Basal Units). Convergence continued during the Carboniferous producing the complex intracontinental deformation that characterizes the Variscan belt.
