Abstract
This paper introduces a two-factor continuous-time model for commodity pricing under the assumption that prices revert to a stochastic mean level, which shows smooth, periodic fluctuations over long periods of time. We represent the mean reversion price by a Fourier series with a stochastic component. We also consider a seasonal component in the price level, an essential characteristic of many commodity prices, which we represent again by a Fourier series. We obtain analytical pricing expressions for futures contracts. Using futures price data on Natural Gas, we provide evidence on the presence of long-term fluctuations and show how to estimate the long-term component simultaneously with a seasonal component using the Kalman filter. We analyse the in-sample and out-of-sample empirical performance of our pricing model with and without a seasonal component and compare it with the Schwartz and Smith (2000) model. Our findings show the in-sample and out-of-sample superiority of our model with seasonal fluctuations, thereby providing a simple and powerful tool for portfolio management, risk management, and derivative pricing.

Abstract

This paper introduces a two-factor continuous-time model for commodity pricing under the assumption that prices revert to a stochastic mean level, which shows smooth, periodic fluctuations over long periods of time. We represent the mean reversion price by a Fourier series with a stochastic component. We also consider a seasonal component in the price level, an essential characteristic of many commodity prices, which we represent again by a Fourier series. We obtain analytical pricing expressions for futures contracts. Using futures price data on Natural Gas, we provide evidence on the presence of long-term fluctuations and show how to estimate the long-term component simultaneously with a seasonal component using the Kalman filter. We analyse the in-sample and out-of-sample empirical performance of our pricing model with and without a seasonal component and compare it with the Schwartz and Smith (2000) model. Our findings show the in-sample and out-of-sample superiority of our model with seasonal fluctuations, thereby providing a simple and powerful tool for portfolio management, risk management, and derivative pricing.

Keywords: Finance, Energy Markets, Seasonality, Long-term swings, Kalman filter.
1. Introduction

Characterising the stochastic behaviour of commodity prices is an issue of special relevance for practitioners in financial markets, since some commodity markets are very liquid and trade high volumes every day. Markets for futures, options, and options on futures with some commodity as the underlying asset are also very active. Commodities are not standard financial assets, so it should not be surprising that they might need specific valuation models. In particular, the characteristics of many commodity products and markets imply a relatively complex pricing nature that may combine short-term seasonal behaviour with fluctuations around a long-term trend. Short-term seasonal fluctuations over an annual period generally reflect changes in demand and supply across the different seasons in a year (Gould et al., 2008; Taylor, 2010). However, changes in production technology or shifts in taste may give rise to long-term trends that cause market prices to fluctuate. Indeed, in line with our argument, Mu and Ye (2015) analysed the crude oil market and found evidence of a long-term trend combined with cyclical movements. The goal of this paper is to propose a model for commodity prices that can help characterise and estimate such components when they are present, without imposing any a priori constraint on their periodicity.

A pioneer contribution in commodity pricing is Schwartz (1997), who proposes a mean-reverting behaviour of commodity prices arguing that, in an equilibrium setting, when prices are relatively high (low) supply will increase (decrease) putting a downward (upward) pressure on prices. With this argument in mind, the author compares three mean-reverting models for the stochastic behaviour of a commodity price: a simple one-factor model for the logarithm of spot prices, a model proposed by Gibson and Schwartz (1990) that adds a second factor accounting for the convenience yield of the commodity, and a further extension that, additionally, incorporates the stochastic behaviour of interest rates as in Vasicek (1977). An interesting variation is the two-factor model in Schwartz and Smith (2000), which specifies log-spot prices as the sum of two state variables representing the equilibrium price level (which is assumed to follow a geometric Brownian motion process) and a short-term deviation from equilibrium prices that reverts towards zero.

The majority of prior research has focused on investigating the impact of a stochastic convenience yield or a jump diffusion process in commodity prices. For example, Casassus et al. (2005) recognized the relevance of expressing the convenience yield as a function of the spot price level and interest rates. Liu and Tang (2011) introduced a stochastic volatility in the convenience yield process and Chiu et al. (2015) also modelled its stochastic behavior. Fouquau and Six (2015) prove theoretically that the two methods commonly used to obtain the convenience yield (filtered from derivative prices or using the interest-adjusted basis an observable proxy) do not provide the same results. Almansour (2016) extended the Gibson and Schwartz (1990) model to allow for regime switching and to account for shifts in the futures term structure. See Lai and Mellios (2016) and references
therein for different analysis of the convenience yield in commodity pricing. In addition to the convenience yield, there exists a considerable body of literature that investigates the relevance of abrupt changes in commodity prices and have analysed the significance of jumps in the processes of these prices. See, for example, Hilliard and Reis (1998), Deng (2001), Yan (2002), Hambly et al. (2009), Mayer et al. (2011), Schmitz et al. (2014), Hilliard and Hilliard (2015), Sévi (2015), Kyriakou et al. (2016), and Gómez-Valle et al. (2017, 2018).

A different strand of literature investigates the impact of seasonal patterns in commodity prices. In this regard, Lucía and Schwartz (2002) provide a simple and clever contribution addressing the seasonal behaviour embedded in many commodity prices. A seasonal component characterised by a deterministic trigonometric function with an imposed annual period is added in an ad-hoc fashion to alternative specifications for the process of log-spot prices, using data from the Scandinavian electricity market for model validation. Cartea and Figueroa (2005) extend this one-factor pricing model specifying a zero level mean-reverting jump-diffusion process for the underlying log-spot price, replacing the trigonometric function in Lucía and Schwartz (2002) by a fifth-order Fourier series. Geman and Nguyen (2005) use soybean prices to analyse the relationship between price volatility and inventories and apply their results to the dynamics of the term structure of soybean forward prices. Borovkova and Geman (2007) proposed a two-factor model that includes the average forward price and the stochastic forward premium. Cartea and González-Pedraz (2012) add a deterministic long-term trend to the spot price process. Finally, Arismendi et al. (2016) introduced a model with seasonal volatility to price commodity options.

Deterministic specifications may be well suited to capture annual seasonality. However, to model swings at the mean level of log-prices over long periods of time, a more promising approach might incorporate them in the behaviour of a mean reversion level for prices. In this regard, using a square-root model representation, Moreno and Platania (2015) incorporate harmonic oscillators to describe the fluctuations in interest rates and their volatility over time. We follow a similar approach by proposing a two-factor extension of the Ornstein-Uhlenbeck specification in which the mean reversion level is represented as a stochastic process with a drift component and a diffusion process that accounts for unexpected noisy shocks. The drift component produces smooth long-term fluctuations that are meant to represent changes in the technology producing the commodity or changes in consumer preferences towards the commodity, while the diffusion process generates fluctuations around the long-run trend.

Many commodities also display seasonal fluctuations around the equilibrium price level that we represent using a Fourier series that enters additively to the process for log-prices. We identify the different components, corresponding to either annual seasonality or longer term components, through the relevant peaks in the power spectrum of futures prices. Under this framework, we
compute closed-form expressions for the prices of futures contracts.¹

Energy markets present a perfect framework to analyse the suitability of models with a seasonal component as well as with long-term fluctuations in the mean reversion level. By nature, many sources of energy can be difficult to store or transport. For instance, the low density of Natural gas makes its storage and transportation highly impractical, so that seasonality has a strong impact on prices, specially, during periods of high demand or production shortages. In addition, there is a number of seasonal variables driving the commodity price (such as business activity, weather conditions, market regulations), and there is extensive research on pricing and hedging energy derivatives and commodities. Some interesting contributions in this area can be found in Kamat and Oren (2002), Geman (2005), Burger et al. (2007), Forsythe (2007), Weron (2007), Cartea and Villaplana (2008), Cartea and Williams (2008), Wong and Lo (2009), Escribano et al. (2011), Carmona and Coulon (2012), Back et al. (2013), Li and Linetsky (2013), Li and Mendoza-Arriaga (2013), Chkili et al. (2014), Janczura (2014), Pellegrino and Sabino (2014), Islyaev and Date (2015), Li et al. (2016), and Ewald at al. (2018), among many others.

With this motivation, we perform an empirical study using our model to price futures contracts on Natural Gas. We provide empirical evidence on the existence of long-term swings together with annual-frequency seasonal components in Natural Gas prices. We apply the Kalman filter on the state-space representation of our model to examine its in-sample fitting ability. Including and excluding the seasonal component in the price level, we can evaluate the relevance of the seasonal component to fit the market prices of energy futures. We also carry out an out-of-sample exercise by using the Kalman filter to obtain one-step ahead forecasts and compare the in-sample and out-of-sample performance of the two versions of our model against the two-factor model in Schwartz and Smith (2000).² Both exercises confirm the superiority of the Fourier model to fit market data as well as to forecast futures prices. Finally, we analyse the economic factors driving the evolution of the long-term swing process. Our findings reveal that business cycle—personal income—and labour market indicators—employment and number of hours—turn out to be significant linear predictors of the mean reversion level in natural gas futures prices.

This paper is organised as follows. Section 2 derives the posited model. Section 3 presents the empirical analysis, where subsections 3.3 and 3.4 present the in-sample and out-of-sample exercises,

¹We make no distinction between futures and forward agreements.
²As described in the academic literature, most multi-factor models are hardly comparable to our model as they propose a stochastic convenience yield or a jump diffusion process. Schwartz and Smith (2000) is the most popular two factor model and it has been chosen as a natural benchmark in many papers, see for instance, Manoliu and Tmpaidis (2002), Sørensen (2002), Lucía and Schwartz (2002), Aiube et al. (2008), Mirantes et al. (2012, 2015), Sbuelz (2015), among others.
respectively, and subsection 3.5 presents the economic determination of the long-term swing process. Finally, section 4 summarises the main findings and provides some concluding remarks.

2. Model with long-term swings and seasonal fluctuations

In this section, we introduce our valuation model for commodity prices, obtaining a closed-form expression for pricing futures contracts. We want our model to incorporate potentially relevant determinants of energy derivative prices in the form of seasonal fluctuations as well as long-term swings in commodity prices.

We represent seasonal fluctuations by a deterministic term entering additively to the stochastic process for log-prices. However, long-term swings may be the effect of structural changes in production technology, preferences, or consumption patterns; we model them as changes in the mean reversion level. The idea is that the mean reversion level of log-prices experiences smooth swings. The observed time series for prices is then interpreted as reflecting short-term fluctuations around this long-term trend for mean prices due to seasonality and purely transitory shocks.

2.1. The general setup

We assume that the stochastic process for the commodity spot price at time $t$, $S_t$, is given by the sum of two components

$$\ln(S_t) = f(t) + Y_t$$

where the $f(t)$ component is a deterministic function accounting for any seasonal behaviour in the commodity price, which is modelled by a Fourier series

$$f(t) = \sum_{n=0}^{\infty} Re\left[A_n e^{i \omega_n t}\right]$$

and the $Y_t$ component follows a mean-reverting process. In this regard, the mean reversion level can be interpreted as a long-run or equilibrium price that depends on the structural and environmental conditions in the energy market. The interesting assumption in our model is that the mean reversion level in $Y_t$ follows a time-dependent process capturing long-term variations in the trend of the log-spot price,

$$dY_t = \kappa (z(t) + \eta_t - Y_t) dt + \sigma_Y dW_t^a$$

$$d\eta_t = \sigma_\eta dW_t^b$$

$$z(t) = \sum_{n=0}^{\infty} Re\left[B_n e^{i \omega_n t}\right] = B_0 + \hat{z}(t)$$

$$\hat{z}(t) = \sum_{n=1}^{\infty} Re\left[B_n e^{i \omega_n t}\right]$$
where $\kappa$, $\sigma_Y$, $\omega_f$, $\omega_z$, $\sigma_\eta$ are positive constants. $W_t^a$ and $W_t^b$ are standard Wiener processes with $dW_t^a dW_t^b = \rho dt$. $B_0$ is the real part of $B_{x,0} + iB_{y,0}$. Note that, for all $n$, $A_n$, $B_n$ are complex numbers, so they include a phase factor. Specifically, consider $A_n = A_{x,n} + iA_{y,n}$ and $B_n = B_{x,n} + iB_{y,n}$ where $A_{x,n}, A_{y,n}, B_{x,n}, B_{y,n} \in \mathbb{R}$. Hence, $A_{x,n}, A_{y,n}, B_{x,n},$ and $B_{y,n}$ denote the amplitude and phase in the Fourier representations for $f(t)$ and $z(t)$, respectively.

Assuming a constant market price of risk in both stochastic processes, $\Lambda(Y_t, t) = \lambda_Y$ and $\Lambda(\eta_t, t) = \lambda_\eta$, $Y_t$ and $\eta_t$ can be represented by the following risk-neutral two-factor process:\(^3\)

\[
\begin{align*}
    dY_t &= \mu_t dt + \sigma_Y d\tilde{W}_t^a \quad (7) \\
    d\eta_t &= -\lambda_\eta \sigma_\eta dt + \sigma_\eta d\tilde{W}_t^b \\
    \mu_t &= \kappa (\alpha + \hat{\zeta}(t) + \eta_t - Y_t) \quad (9) \\
    \alpha &= B_0 - \frac{\lambda_Y \sigma_Y}{\kappa} \quad (10)
\end{align*}
\]

where $\tilde{W}_t^a = W_t^a + \lambda_Y t$ and $\tilde{W}_t^b = W_t^b + \lambda_\eta t$ are standard Wiener processes under the risk-neutral measure $\tilde{P}$. In addition, note that under the risk-neutral measure the process for $\eta_t$ has a deterministic drift component determined by the product of the market price of risk of the stochastic mean reverting process and the volatility level in the long-run price.

Conditional on information available at time $t$, the logarithm of the commodity spot price at time $T$ ($T > t$) follows a normal distribution. Under the risk-neutral probability measure $\tilde{P}$, the conditional mean and variance of that distribution are,

\[
\begin{align*}
    \tilde{E} [\ln (S_T) | \mathcal{F}_t] &= f(T) + e^{-\kappa(T-t)} (\ln (S_t) - f(t)) + \left(1 - e^{-\kappa(T-t)}\right) \left(\alpha + \left(\frac{1}{\kappa} + t\right) \lambda_\eta \sigma_\eta + \eta_t\right) \\
    &\quad - \lambda_\eta \sigma_\eta \left(T - t e^{-\kappa(T-t)}\right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + in\omega_z} \left( e^{in\omega_z T} - e^{-\kappa(T-t) + in\omega_z t}\right) \right] \quad (11) \\
    \tilde{V} [\ln (S_T) | \mathcal{F}_t] &= \Sigma_T^2 = \sigma_\eta^2 \left[T - t - \frac{2}{\kappa} \left(1 - e^{-\kappa(T-t)}\right) + \frac{1}{2\kappa} \left(1 - e^{-2\kappa(T-t)}\right)\right] \\
    &\quad + \frac{\sigma_\eta^2}{2\kappa} \left(1 - e^{-2\kappa(T-t)}\right) + \frac{2\sigma_Y \sigma_\eta \rho}{\kappa} \left[\left(1 - e^{-\kappa(T-t)}\right) - \frac{1}{2} \left(1 - e^{-2\kappa(T-t)}\right)\right] \quad (12)
\end{align*}
\]

where we have applied the isometry property for stochastic integrals in the variance. Obtaining the forward price of a commodity maturing at time $T$ is a straightforward application of the properties of the log-normal distribution under the risk-neutral measure. Hence, the following proposition holds.

---

\(^3\)Assuming a constant market price of risk is a common practice in this type of modelling exercise. See, for instance, Schwartz (1997), Schwartz and Smith (2000), or Lucia and Schwartz (2002).
Proposition 2.1. The forward price at time \( t \) of a commodity maturing at time \( T \) is given by:

\[
F(S_t, t, T) = \mathbb{E} [S_T | \mathcal{F}_t] = \exp \left\{ \mathbb{E} [\ln (S_T) | \mathcal{F}_t] + \frac{1}{2} \tilde{V} [\ln (S_T) | \mathcal{F}_t] \right\}
\]

\[
= \exp \left\{ f(T) + e^{-\kappa(T-t)} (\ln (S_t) - f(t)) + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma \eta \right) - \lambda \eta \sigma \eta \left( T - te^{-\kappa(T-t)} \right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + in\omega z} \left( e^{in\omega z T} - e^{-\kappa(T-t)+in\omega z t} \right) \right] + \frac{1}{2} \Sigma_T^2 \right\}
\]

where \( \Sigma_T^2 \) is given as in equation (12). Alternatively,

\[
\ln(F(S_t, t, T)) = f(T) + e^{-\kappa(T-t)} (\ln (S_t) - f(t)) + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma \eta \right) - \lambda \eta \sigma \eta \left( T - te^{-\kappa(T-t)} \right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + in\omega z} \left( e^{in\omega z T} - e^{-\kappa(T-t)+in\omega z t} \right) \right] + \frac{1}{2} \Sigma_T^2
\]

Then, the log-futures price turns out to be made up of four components:

i) A correction on the log-spot price, \( e^{-\kappa(T-t)} \ln (S_t) \).

ii) The effect from a periodic component that we interpret as incorporating seasonal fluctuations, \( f(T) - e^{-\kappa(T-t)} f(t) \).

iii) The effect from the level of noise variance of the two stochastic processes, \( 1 - e^{-\kappa(T-t)} \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma \eta - \lambda \eta \sigma \eta \left( T - te^{-\kappa(T-t)} \right) + \frac{1}{2} \Sigma_T^2 \), and

iv) The influence of the time-varying mean reversion level:

\[
\left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \eta t \right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + in\omega z} \left( e^{in\omega z T} - e^{-\kappa(T-t)+in\omega z t} \right) \right]
\]

The last three components tend toward zero as we approach the maturity of the futures contract, and, at \( t = T \), we will have \( F(S_T, T, T) = S_T \), as expected.

It is also convenient to see the theoretical futures price as the aggregate of two functions:

\[
\ln(F(S_t, t, T)) = M(S_t, t, T; \theta_M) + N(t, T; \theta_N), \text{ with:}
\]

\[
M(S_t, t, T; \theta_M) = e^{-\kappa(T-t)} \ln (S_t) + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma \eta \right) - \lambda \eta \sigma \eta \left( T - te^{-\kappa(T-t)} \right) + \frac{1}{2} \Sigma_T^2
\]

---

4See Appendix of proofs

5Notice that \( \Sigma_T^2 \) is the variance of futures prices at time \( T \), conditional on the information available at time \( t \). As \( t \) goes to \( T \), that variance converges to zero.
that depends on the spot price as well as on time to maturity, and

\[
N(t, T; \theta_N) = \sum_{n=0}^{\infty} \text{Re} \left[ A_n \left( e^{i\omega_n T} - e^{-\kappa(T-t)+i\omega_n t} \right) \right] + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + i\omega_z} \left( e^{i\omega_z T} - e^{-\kappa(T-t)+i\omega_z t} \right) \right] \tag{17}
\]

with the structural parameter vector \( \theta_M = (\alpha, \sigma_Y, \lambda_\eta, \kappa) \), and the seasonal parameter vector \( \theta_N = (\kappa, \{A_n\}_{n=0}^{\infty}, \omega_f, \{B_n\}_{n=1}^{\infty}, \omega_z) \).

The first term in \( M(S_t, t, T; \theta_M) \) depends on spot prices and the following terms are corrections by time to maturity and by the level of risk. For the maturities that we consider, the power functions of \( T - t \) are essentially constant along the sample. Thus, \( M(S_t, t, T; \theta_M) \) reproduces the behaviour of spot prices and is a relevant driver of the shape of the forward/futures curve.

However, \( N(t, T; \theta_N) \) describes seasonal fluctuations in futures price and the time evolution of the mean-reversion futures price level. Its analytical representation reflects the Fourier series structure of \( f(t) \) and \( z(t) \), so this function is stationary in nature.

2.2. Particular cases

Now, we propose two different particular specifications from the previous setup:

- **Fourier model** emerges from the general setup above when we incorporate a Fourier series with a single term for the mean reversion level, through the second term in \( N(t, T; \theta_N) \), and do not consider the \( f(t) \) function, so that \( \ln(S(t)) = Y_t \), and the \( N(t, T; \theta_N) \) function becomes:

\[
N(t, T; \theta_N) = \text{Re} \left[ \frac{\kappa B}{\kappa + i\omega_z} \left( e^{i\omega_z T} - e^{-\kappa(T-t)+i\omega_z t} \right) \right] \tag{18}
\]

- **Fourier model with one seasonal component** adds to the previous specification a Fourier series representation for \( f(t) \), again with a single frequency, to capture either seasonal component, so that the \( N(t, T; \theta_N) \) function becomes:

\[
N(t, T; \theta_N) = \text{Re} \left[ A \left( e^{i\omega_f T} - e^{-\kappa(T-t)+i\omega_f t} \right) \right] + \text{Re} \left[ \frac{\kappa B}{\kappa + i\omega_z} \left( e^{i\omega_z T} - e^{-\kappa(T-t)+i\omega_z t} \right) \right] \tag{19}
\]

Our empirical exercise consists of estimating each model using daily observations of futures contracts written on Natural Gas. By considering nested model specifications, we can easily analyse the contribution of the seasonal component and the long-term swings in the mean reversion price to fitting futures pricing data. While the main determinant of the level of fitted futures prices is the presence of the spot price process in \( M(S_t, t, T; \theta_M) \), we see that all the other terms also matter to achieve a good data fit. However, the contribution of the noise variance, incorporated in the last term in \( M(S_t, t, T; \theta_M) \), is generally a minor contribution, as shown below.

We start by examining the power spectrum of prices for each futures contract to offer initial evidence on the presence of periodic terms of different natures. We let the data suggest the relevant
frequencies without restricting the range of frequencies to be estimated from observed futures pricing data; we take the estimated short frequencies (long periods) as corresponding to the long-term swing process.

3. Empirical Analysis

The aim of this section is to provide a comprehensive description of the prices in the Natural Gas commodity markets. The underlying hypothesis is that the price of Natural Gas has an inherent structure, including seasonal fluctuation and long-term swings in the mean reversion level, shared by every available futures contract.

Furthermore, we analyse the in-sample and out-of-sample empirical performance of the Fourier model and the Fourier model with a seasonal component against the Schwartz and Smith (2000) model.

3.1. The data

The data set used for the empirical study consists of daily observations of prices for futures contracts Ng-5, Ng-8, Ng-12, Ng-18, and Ng-24 written on Natural Gas traded on the New York Mercantile Exchange (NYMEX). The figures in the mnemonics of each contract signal the number of months to maturity. For instance, Ng-5 represents the fifth contract closest to maturity, and so on. All the time series have been extracted from Datastream. We take Henry Hub as the pricing point for natural gas futures contracts. Table 1 presents some data statistics.

Table 1: Key statistics for each futures contract written on Natural Gas

Moreover, table 2 presents the augmented Dickey-Fuller (ADF) test statistic for the logarithm of prices for Natural Gas futures as well as for the first difference of each series. Clearly, the unit root hypothesis cannot be rejected for the price level at any time to maturity, meaning that futures prices are non-stationary. However, the presence of a unit root is rejected when considering the first difference of each price series.

Test model: \( y_t = c + \delta t + ay_{t-1} + \sum_{i=1}^{10} b_i \Delta y_{t-i} + \epsilon_t \)

Table 2: Augmented Dickey-Fuller test for the logarithm of futures prices and for the first difference of each price series. For the time series in first differences, we impose \( \delta = 0 \) in the test model.

The possible existence of periodic patterns suggests the convenience of analysing the spectral density of futures prices. Figure 1 presents the Natural Gas pricing surface, while Figure 2 displays the spectral density for each of the five Natural Gas futures contracts considered. The maximum at the zero frequency reflects the existence of a unit root in the price series. Interestingly, the five time series of futures prices reach additional peaks in their spectral density at other low frequencies, indicating the presence of additional medium- to long-term components driving the behaviour of these prices.

We do not impose any restriction on the range of numerical frequencies to be estimated. Consistent with our interpretation of the theoretical model, we associate the lowest estimated frequency to the Fourier term representing the mean reversion level. To estimate the Fourier model without a seasonal component, we consider a single frequency in the estimation. For the Fourier model with a seasonal component, we consider two frequencies: a short one (long period) corresponding to the Fourier component in the level of mean reversion, and a higher frequency (shorter period) that we assign to the \( f(t) \) function.
3.2. State-space representation

Any theoretical model explaining the formation of futures prices assumes a specific relationship between spot and futures prices, as we have described in the previous sections for alternative models
of energy futures prices. However, as we observe in Figures 1 and 3, spot Natural Gas market
data experience frequent and pronounced spikes that are not reflected in data for futures prices. In
addition, we observe dates where there is a remarkable discrepancy between spot and futures prices,
even for those futures closest to maturity - as shown in Figure 3. In this regard, Table 7 lists the
dates with the significant discrepancies between the spot and futures prices. Spot prices present
spikes or jumps on most of those dates. Table 7 also provides a description of unusual or remarkable
events that could have affected the energy market equilibrium. These gaps between spot and futures
prices suggest that while the fundamental and theoretical evolution of energy prices is shared by
prices in the spot and futures markets, spot prices incorporate some idiosyncratic jump element that
is not reflected in futures prices. Hence, a direct linear relationship between the two observed price
series would face that inconsistency, hindering the empirical characterisation of such a relationship.
To avoid this empirical difficulty, we assume that spot prices are not directly observed and embed
spot and futures prices in a state-space representation that we estimate using the Kalman Filter,
see Hamilton (1994).

Given the analytical expressions for futures prices obtained in Section 2 and Appendix A, we
represent each model as,

- Schwartz and Smith (2000) model:
– Observation equation:

\[ x_t = A_t + H_t [\chi_t, \xi_t]^T + \epsilon_t \quad (20) \]

– State equation:

\[ [\chi_{t+1}, \xi_{t+1}]^T = G_t + F_t [\chi_t, \xi_t]^T + \epsilon_{t+1} \quad (21) \]

where

\[ x_t = \ln(F(S_t, t, T)) \quad (22) \]
\[ A_t = A(T - t) \quad (23) \]
\[ H_t = \begin{bmatrix} e^{-\kappa(T-t)} & 1 \end{bmatrix} \quad (24) \]
\[ G_t = \begin{bmatrix} 0, & \mu_{\xi} dt \end{bmatrix} \quad (25) \]
\[ F_t = \begin{bmatrix} e^{-\kappa(T-t)} & 0 \\ 0 & 1 \end{bmatrix} \quad (26) \]
\[ E[\epsilon_t] = 0 \quad (27) \]
\[ Var[\epsilon_t] = \begin{bmatrix} \left(1 - e^{-2\kappa dt}\right) \frac{\sigma^2}{2\kappa} & \left(1 - e^{-\kappa dt}\right) \frac{\rho_{\chi\xi} \sigma_\chi \sigma_\xi}{\kappa} \\ \left(1 - e^{-\kappa dt}\right) \frac{\rho_{\chi\xi} \sigma_\chi \sigma_\xi}{\kappa} & \sigma^2 \xi dt \end{bmatrix} = Q \quad (28) \]

– Fourier model and Fourier model w/seasonal component:

– Observation equation:

\[ x_t = A_t + H_t [Y_t, \eta_t]^T + \epsilon_t \quad (29) \]

– State equation:

\[ [Y_{t+1}, \eta_{t+1}]^T = G_t + F_t [Y_t, \eta_t]^T + \epsilon_{t+1} \quad (30) \]
where

\[
\begin{align*}
Y_t &= \ln(S_t) \\
A_t &= \left(1 - e^{-\kappa(T-t)}\right) \left(\alpha + \left(\frac{1}{\kappa} + t\right) \lambda \sigma \eta \right) - \lambda \sigma \eta \left(T - te^{-\kappa(T-t)}\right) + \Re \left[\frac{\kappa B}{\kappa + i\omega \eta} \left(e^{i\omega \eta T} - e^{-\kappa(T-t) + i\omega \eta t}\right)\right] + \frac{1}{2} \Sigma_T^2 \\

\text{Fourier} &= \left\{ \begin{array}{ll}
Y_t &= \ln(S_t) \\
A_t &= \left(1 - e^{-\kappa(T-t)}\right) \left(\alpha + \left(\frac{1}{\kappa} + t\right) \lambda \sigma \eta \right) - \lambda \sigma \eta \left(T - te^{-\kappa(T-t)}\right) + \Re \left[\frac{\kappa B}{\kappa + i\omega \eta} \left(e^{i\omega \eta T} - e^{-\kappa(T-t) + i\omega \eta t}\right)\right] + \frac{1}{2} \Sigma_T^2
\end{array} \right. \\
\text{Fourier w/ seasonal component} &= \left\{ \begin{array}{ll}
Y_t &= \ln(S_t) - \Re \left[\lambda e^{i\omega \eta t}\right] \\
A_t &= \Re \left[\lambda e^{i\omega \eta t}\right] + 1 - e^{-\kappa(T-t)} \left(\alpha + \left(\frac{1}{\kappa} + t\right) \lambda \sigma \eta \right) - \lambda \sigma \eta \left(T - te^{-\kappa(T-t)}\right) + \Re \left[\frac{\kappa B}{\kappa + i\omega \eta} \left(e^{i\omega \eta T} - e^{-\kappa(T-t) + i\omega \eta t}\right)\right] + \frac{1}{2} \Sigma_T^2
\end{array} \right. \\
x_t &= \ln(F(S_t, t, T)) \\
H_t &= \left[e^{-\kappa(T-t)}, 1 - e^{-\kappa(T-t)}\right] \\
G_t &= \left[\kappa z(t) dt, 0\right] \\
F_t &= \left[\begin{array}{cc}
1 - \kappa dt & \kappa dt \\
0 & 1
\end{array}\right] \\
E[\epsilon_t] &= 0 \\
\text{Var}[\epsilon_t] &= \left[\begin{array}{cc}
\sigma_Y^2 dt & \sigma_Y \sigma \eta \rho dt \\
\sigma_Y \sigma \eta \rho dt & \sigma^2 \eta dt
\end{array}\right] = Q
\end{align*}
\]

3.3. Estimation with Natural Gas data

3.3.1. Numerical results

Table 3 presents estimated parameters and their standard deviations for each model over the whole sample, along with measures to compare the relative quality of each model: the maximised log-likelihood from the Kalman filter estimation, the Akaike information criterion (AIC), an estimate of the standard deviation of pricing errors, \(\left(\frac{1}{T} \sum_t \hat{u}_t^2\right)^{1/2}\), and the sum of squared residuals, \(\sum_t \hat{u}_t^2\). The results are conclusive: compared with the benchmark model, the different specifications of Fourier terms in the stochastic process for log-spot prices dramatically improve the in-sample fitting of futures prices. Specifically, we observe that the Fourier model almost halves the aggregated squared residuals of Schwartz and Smith—a 47% reduction—and when compared to the Fourier model w/seasonal component, the reduction is even greater—an 81% reduction over the benchmark model. We also use the AIC as an estimator of the relative quality of the Fourier model over the benchmark model. Even though the AIC penalises those models with a higher number of parameters, we observe that both specifications of the Fourier model provide lower AIC values than Schwartz and Smith. These results suggest the superior performance of both specifications of the Fourier model over the benchmark model, with a clear dominance of the Fourier with a seasonal component model.
Although the Schwartz and Smith model and the Fourier model—w/ and w/o seasonal component—belong to the family of two-factor models, the theoretical background and modelling behind them is essentially different. The objective of the Fourier model is to account for long-term swings in the mean reversion level as well as for seasonal patterns in energy markets, while the Schwartz and Smith model aims to describe the evolution of the equilibrium price level and short-term deviations—see sections 4 and 2. Even though comparing the in-sample and out-of-sample performance provides a meaningful and valid empirical appraisal of each model, the theoretical background prevents us from comparing the estimated parameters between Schwartz and Smith and the Fourier models. As we observe in table 3, the estimated parameters in the Fourier and Fourier w/seasonal component are quite stable, in particular, we observe the presence of a consistent long-term swing of 19-19.5 years in both models. In addition, the seasonal Fourier model also presents a seasonal component with a one-year period. In both models we observe a higher variance level in futures prices than in the long-run mean reversion level, that is $\sigma_Y > \sigma_\eta$, as should be expected from our theoretical model. In effect, long-run mean reversion prices can be regarded as equilibrium prices that depend on structural and environmental conditions, such as production technology or consumption preferences, and, therefore, are subject to a lower volatility level and shocks than current prices. In addition, interestingly, is the correlation between futures prices and the long-run mean reversion price, which we estimate is 30.54% and 41.13% for the Fourier and the seasonal Fourier model, respectively. Indeed, the long-term mean reversion price level depends on structural and environmental conditions, but does not depend on short-term or seasonal fluctuations. The simplest version of the Fourier model does not incorporate these short-term and seasonal fluctuations in prices. Hence, the idiosyncratic component in futures prices will be somewhat affected by these fluctuations—which are present in prices but not in the long-run level—resulting in an underestimation of the correlation parameter. In contrast to the Fourier model, the Fourier model w/seasonal component successfully identifies and incorporates the effect of seasonal fluctuations; hence, after accounting for these effects, the correlation between prices and the long-run level increases. Finally, the pair of parameters $(B_x, B_y)$ and $(A_x, A_y)$ define the amplitude and phase in the long-term swing and seasonal component, respectively. We analyse the impact of these components in the next section.

Table 3: \( \sum_{t=1}^{T} u_t^2 \) is the sum of squared pricing errors, \( \left( \frac{1}{T} \sum_{t=1}^{T} u_t^2 \right)^{1/2} \) is an estimate of the residual standard deviation, and AIC is the Akaike information criterion.

### 3.3.2. Model analysis

The better overall fit to the data, especially when incorporating a seasonal component, means that the Fourier specification does a better job in jointly reproducing the long-term swings in the mean together with the seasonal components that might be present in Natural Gas futures price data. In addition, we want to advance the understanding of the role of the different components of the pricing model to explain futures prices. To that end, using data from the Ng-18 futures contract, Figure 4 decomposes fitted futures prices from the seasonal Fourier model to show the contribution
of each component. The upper-left graph displays observed and filtered spot prices, while the lower-left graph shows estimated and observed futures prices (all in logs). Spot prices present a higher short-term volatility than futures prices due to the presence of important spikes in spot prices that are not reproduced in futures prices. Given the close association between spot and futures prices in our pricing formula, the filtered spot price process closely reproduces the time evolution of the observed spot prices, but cannot reproduce their spikes. If we had used observed spot prices rather than filtered spot prices to estimate the model, these spikes would have produced significant fitting errors in futures prices. The lower-right graph displays the evolution of each term in the Fourier model with the seasonal component: i) the spot-price effect, $e^{-\kappa(T-t)}\ln(S_t)$, ii) the effect from the periodic component, $Re \left[A e^{i\omega_f T} - e^{-\kappa(T-t)}Re [A e^{i\omega_f t}] \right]$, iii) the volatility effect in both stochastic terms, $\left(1 - e^{-\kappa(T-t)}\right) \left(\frac{1}{\kappa} + t\right) \lambda_t \sigma_t \eta_t - \lambda_t \eta_t \left(T - te^{-\kappa(T-t)}\right) + \frac{1}{2} \Sigma_t^2$, iv) the effect of the time-varying mean reversion level, $\left(1 - e^{-\kappa(T-t)}\right) (\alpha + \eta_t) + Re \left[\frac{\kappa B}{\kappa + i\omega_z} \left(e^{i\omega_z T} - e^{-\kappa(T-t)+i\omega_z t}\right)\right]$. The volatility effect can be regarded as a level effect of minor contribution compared with the other components. In addition, the time-varying mean-reversion level reproduces to a good extent the level of futures prices while the periodic effect is a sinusoid that provides the right time pattern to reproduce the evolution of futures prices.

Figure 4: The upper-left row shows observed and filtered spot prices, both in logs. The upper-right row shows the process followed by the LTS = $z(t) + \eta_t$ obtained using Kalman Filter. The lower left graph shows observed and fitted futures prices. The lower right graph displays: i) the effect of spot prices, ii) the seasonal component, iii) the volatility effect, iv) the effect of the long-term mean reversion price level.

19
Now, we consider the behaviour of the $N(t, T; \theta_N)$ function, which is a filtered signal for the behaviour of futures prices after taking into account the effect of spot prices, the time-varying mean reversion level, and the volatility effect. The upper graph of Figure 5 shows this function together with the adjustment from the Fourier model. Clearly, the Fourier term for the long-run mean reversion level captures the time evolution of a general trend although, as expected, it does not reproduce the short-term seasonal fluctuations. Indeed, it is striking that after having discounted the influence of spot prices, the $N(t, T; \theta_N)$ function may display such a clear seasonal effect with an apparent annual period. The Fourier model with a seasonal component is able to capture this seasonal pattern by adding a Fourier term with a single frequency for either a seasonal or a cyclical component in $f(t)$ (middle graph). Finally, the lower graph presents the power spectral density, where we easily identify a short frequency describing a long-term fluctuation and a second spectral peak with an annual frequency.

![Figure 5: The upper and middle graphs display the $N(t, T; \theta)$ function together with the Fourier component estimated in the Fourier and Fourier w/seasonal model, respectively. The lower graph shows the $N(t, T; \theta)$ function power spectral density for the Ng-18 futures contract.](image)

3.4. Out-of-Sample Analysis

We have just seen the improvement achieved by our Fourier-based model for in-sample fitting relative to a more standard alternative. In this section we examine whether our model also helps in anticipating changes in Natural Gas futures markets. To this end, we compare the one-day forecasting performance of the Fourier model and the Fourier model with a seasonal component
with that of the Schwartz and Smith model over three full years - 2012, 2013, and 2014. To obtain forecast futures prices over 2012, we start by estimating each model - equations (20) and (29) - using data up to 31/12/2011. After that, we initiate the Kalman Filter algorithm and obtain one-day ahead forecasts for futures prices over 2012 using the state-space representation presented in section 3.2,

$$\hat{x}_{t+1|t} = E(x_{t+1}|F_t) = A_{t+1} + H_{t+1} \left[ \hat{Y}_{t+1|t}, \hat{\eta}_{t+1|t} \right]^T$$

(39)

with associated mean square error

$$E \left[ (x_{t+1} - \hat{x}_{t+1|t})(x_{t+1} - \hat{x}_{t+1|t})^T \right]$$

(40)

and we run the process for the entire year. For a detailed explanation on the Kalman Filter, we recommend Hamilton (1994).

To obtain forecasts for 2013, we estimate each model using data up to 31/12/2012. The same recalibration procedure is applied to obtain one-day ahead forecasts for futures prices over 2014. Table 4 summarises the results. We observe that the Schwartz and Smith model and the simpler version of the Fourier model achieve the minimum sum of squares of forecast errors in 4 of the 15 (maturity, year)-pairs. The Fourier model with a seasonal component attains the minimum sum of squared forecast errors in the remaining seven cases. Thus, the Fourier model with a seasonal component specification obtains the best forecasting performance in most (maturity, year)-pairs. When we aggregate over time in the last column, the Fourier model with a seasonal component is the best performing model for all maturities. Furthermore, the reduction in forecasting errors is large, especially relative to the Schwartz and Smith model. If we aggregate across maturities in the last row of each panel, the Fourier model with a seasonal component has the best performance for 2012 and 2014, with the simpler version of the Fourier model being best for 2013, although by a small margin. It is also interesting to analyse the mispricing in terms of dollar value. Table 5 presents the average dollar mispricing committed by each model. We observe that both versions of the Fourier model consistently outperform the benchmark, with the Fourier model w/seasonal component providing more stable and reliable predictions of futures prices. These results are very encouraging and suggest the convenience of using our model specification to forecast future Natural Gas prices against more standard alternative specifications.

Table 5: Realised average dollar mispricing by each model (in USD units)
3.5. The economic determinants of long-term swings (LTS)

If our model is successful, the estimate of the underlying price level that the market reverts to should reflect the evolution of the energy market, as well as the possible reaction to business cycle events. To analyse this, in this section, we estimate a set of regression models explaining the time series of the LTS = \( z(t) + \eta_t \) process provided in equation (3) and empirically obtained in section 3.3. The independent variables considered here are:

1. NATLGAS: Henry Hub spot prices as traded on the New York Mercantile Exchange (NYMEX)\(^7\)
2. CRUDEOIL: Crude Oil spot prices as traded on the New York Mercantile Exchange (NYMEX)\(^7\)
3. STORAGE: US working Natural gas underground storage, including US totals and regional breakdowns\(^8\)
4. INCOME: US Personal income excluding transfer receipts chained 2012 Dollars SAAR\(^8\)
5. TOT_EMPL: US employment total in labour force, seasonally adjusted\(^8\)
6. HOURS: US average weekly hours non-farm total private production and non-supervisory, seasonally adjusted\(^8\)

In section 3.3, we obtained daily estimates of LTS. We now consider the end-of-month values of LTS between January 1994 and January 2015, with 253 monthly observations. Table 6 shows the adjusted R-squared statistic for each regression model. All the variables are in logarithms and all the estimated coefficients are significant at the 1% significance level. The first regression shows that mean reversion prices are strongly correlated with the spot prices of Natural Gas and Crude Oil. This is to be expected, since LTS is estimated from Natural Gas futures prices. In addition, given the energy market interdependence we might expect a strong correlation between the Natural Gas and Crude Oil markets. The second regression shows a significant correlation also with personal income, one of the main business cycle indicators. We do not include employment in that regression because of its high correlation with personal income (correlation=0.98). The third regression uses as explanatory variables some labour market indicators: employment and hours. They achieve an even higher explanatory power than income and, it is, in fact, quite remarkable that long-run mean reversion prices are so strongly correlated with business cycle indicators. The coefficient in hours is negative, given its well-known negative correlation with employment. The fourth regression shows that income has additional explanatory power to that contained in the labour market indicators.

\(^7\) Obtained from Datastream
\(^8\) Obtained from Bloomberg
The collinearity in that regression justifies the negative sign of the income coefficient. The final regression, again subject to collinearity, achieves an explanatory power better than the regression on energy prices alone. Finally, figure 6 presents a visual comparison of the results obtained using the energy market regression model (1) and the full regression model (5). Even though both models reproduce the evolution of long-term mean reversion prices quite well, it is clear that income and job market variables help to reduce the spikes present in the energy spot market, providing a much smoother and accurate representation of the long-term mean reversion process.

\[9\] Collinearity precludes us from giving a strong interpretation of individual coefficient estimates, but it does not bias the overall measures of fit of the regression model.

Table 6: Least-squares estimates (standard deviation in parentheses) of five regression models explaining the relationship between the long-term swing process \(LTS = z(t) + \eta_t\) in Natural Gas futures prices and economic conditions. For each model, we present the adjusted R-squared statistic, the root-mean-square error (Root MSE), and the F-test for global significance.
4. Conclusions

Changes in the production technology or shifts in preferences may cause long-run swings in commodity prices. We view such changes as influencing the mean reversion level of commodity prices and we incorporate that feature into a continuous-time Ornstein-Uhlenbeck model for the logarithm of commodity spot prices. In our model, the mean reversion price level experiences such long-term swings, represented by a Fourier series, as well as purely random shocks, represented by a diffusion process. Thus, we have a two-factor model for commodity prices. In addition, we consider the possibility of seasonal fluctuations in the observed level of spot prices, which we represent by a second Fourier series.

Our model is analytically tractable and allows closed-form expressions for the price of futures contracts. It nests the one-factor models by Schwartz (1997) and Lucía and Schwartz (2002), preserving their analytical tractability and allowing a more flexible representation of the time evolution of commodity spot prices. We have examined in detail the empirical performance of two versions of our model, with and without a seasonal component, against the two-factor model in Schwartz and Smith (2000) using prices of futures contracts on Natural Gas at different maturities. To identify the relevant frequencies driving futures prices and their associated periods, we first conducted a spectral analysis of each futures contract. The models are estimated in state-space representation using the Kalman Filter.

Even in its simplest representation, without the seasonal component in the observed spot prices, our model outperforms Schwartz and Smith (2000), providing a better and more reliable fitting to observed futures prices. Thus, the extension incorporated in our model seems to be quite relevant for
price modelling. Allowing for a seasonal component leads to still significant additional improvements in fitting the data. Furthermore, we have also performed an out-of-sample analysis where, again, our model provides significant improvement over the benchmark, achieving better predictions in most cases.

The main improvement in the fitting ability of our model comes from allowing long-term swings in the mean reversion level. Furthermore, without imposing any restriction or prior belief on the frequencies to be estimated from the Fourier series for the different components, our model is quite successful in capturing a seasonal component whenever it is present in the data. The model should also be appropriate for modelling other types of commodities with specific seasonal components, like agricultural products.

References

Appendix A

This appendix introduces the benchmark model that we use in our empirical analysis. The model was presented by Schwartz and Smith (2000).

This model assumes that the commodity spot price is given by the decomposition of two stochastic factors as

\[
\ln (S_t) = \chi_t + \xi_t \tag{41}
\]

where \(\xi_t\) represents the equilibrium price level process and \(\chi_t\) the short-term deviation from the equilibrium price level. Under this framework, the authors assume that short-term deviations follow a zero mean reverting process given as

\[
d\chi_t = -\kappa \chi_t dt + \sigma_\chi dW^a_t \tag{42}
\]

while the equilibrium price level is assumed to follow a Brownian motion process given as

\[
d\xi_t = \mu_\xi \xi_t dt + \sigma_\xi dW^b_t \tag{43}
\]

where \(dW^a_t\) and \(dW^b_t\) are standard Wiener processes with \(dW^a_t dW^b_t = \rho \kappa \xi dt\).

Assuming a constant market price of risk for the equilibrium price level and short-term deviation process, the risk-neutral processes are given as

\[
d\chi_t = (-\kappa \chi_t - \lambda_\chi \chi_t) dt + \sigma_\chi d\tilde{W}^a_t \tag{44}
\]

\[
d\xi_t = (\mu_\xi - \lambda_\xi \xi_t) dt + \sigma_\xi d\tilde{W}^b_t \tag{45}
\]

Under the risk-neutral measure the log-spot price process is normally distributed, hence the forward price at time \(t\) of a contract maturing at time \(T\) is given as

\[
F(S_t, t, T) = \tilde{E} [S_T | \mathcal{F}_t] = \exp \left\{ \tilde{E} [\ln (S_T) | \mathcal{F}_t] + \frac{1}{2} \tilde{V} [\ln (S_T) | \mathcal{F}_t] \right\} \tag{46}
\]

where

\[
\tilde{E} [\ln (S_T) | \mathcal{F}_t] = e^{-\kappa(T-t)} \chi_t + \xi_t + \mu_\xi (T-t) \left( 1 - e^{-\kappa(T-t)} \right) \frac{\lambda_\chi}{\kappa} \tag{47}
\]

\[
\tilde{V} [\ln (S_T) | \mathcal{F}_t] = \left( 1 - e^{-2\kappa(T-t)} \right) \frac{\sigma_\chi^2}{2\kappa} + \sigma_\xi^2 (T-t) + 2 \left( 1 - e^{-\kappa(T-t)} \right) \frac{\rho \kappa \sigma_\chi \sigma_\xi}{\kappa} \tag{48}
\]

hence, the logarithm of futures prices can be represented as

\[
\ln (F(S_t, t, T)) = e^{-\kappa(T-t)} \chi_t + \xi_t + A(T, t) \tag{49}
\]
and

\[
A(T,t) = \mu_\xi^*(T-t) - \left(1 - e^{-\kappa(T-t)}\right) \frac{\lambda_\chi}{\kappa} \\
+ \frac{1}{2} \left(1 - e^{-2\kappa(T-t)}\right) \frac{\sigma_\chi^2}{2\kappa} \beta \chi \xi(T-t) + 2 \left(1 - e^{-\kappa(T-t)}\right) \frac{\rho_\chi \xi \sigma_\chi \xi}{\kappa}
\]

(50)

\[
\mu_\xi^* = \mu_\xi - \lambda_\xi
\]

(51)

10 On January 1994, North America suffered a severe cold wave. It started in the northern United States and southern Canada on January 18, 1994. On January 17, 1994, the Northridge earthquake occurs, considered one of the worst natural disasters in the U.S.

11 On 14 December 1995, the General Framework Agreement for Peace (GFAP) is signed in Paris, after it was negotiated in Dayton, Ohio. On 16 December, the Alliance’s North Atlantic Council launches the largest military operation ever undertaken by the Alliance, Operation Joint Endeavour. Based on UN Security Council Resolution 1031, NATO is given the mandate to implement the military aspects of the Peace Agreement. A NATO-led multinational force, called the Implementation Force (IFOR), starts its mission on 20 December 1995. IFOR is given a one-year mandate.

12 On January 1996, the ‘Blizzard of 1996’ occurs. It affects the Northeast part of the U.S. and is considered one of the most devastating winter storms ever. The blizzard is followed by a subsequent warm-up along with heavy rain which triggers major flooding during the first and second week of 1996.

14 Temperatures during the first half of February 1996 are much colder than normal and low storage levels raise concerns about supply. In fact, on February 2, 1996, Henry Hub's spot price reaches $12.5$/MMBTU, a ridiculously high price if we consider that the average spot price is $1.58$/MMBTU in February 1995, $2.58$/MMBTU in February 1994, and $2.22$/MMBTU in February 1997.

15 On February 9, 1996, the Canary Wharf bombing occurs. The Irish Republican Army declares the end of the ceasefire and detonates a truck bomb in Canary Wharf.

16 The U.S. Embassy in Athens is attacked.

17 The United Nations Security Council Resolution 1330 concerning the Oil-for-Food programme is unanimously adopted and extends provisions relating to the export of Iraqi petroleum or petroleum products in return for humanitarian aid.

---

**19** United States, United Kingdom and Spain present to the UN Security Council a resolution stating that Iraq ‘had failed to take the final opportunity to disarm’. Rumours of an impending war drive down stock markets all over the world, while many commodity prices increase to historical maxima. The Henry Hub spot price closes at 19.38$/MMBTU, when the average spot price had oscillated around 5$/MMBTU.

**20** On December 6, the first major winter storm strikes the North Eastern United States.

**21** A report from the International Monetary Fund expresses alarm regarding mounting budget deficits in the United States due to a recession, tax cuts, and spending for the war on terrorism.

**23** In mid-2006, crude oil is traded for over USD 79 per barrel (bbl), setting an all-time record.

**24** Extreme weather in Europe kills nine people in Germany, traps a Eurostar train in the Channel Tunnel, disrupts flights at international airports in Amsterdam, Dublin, Knock, and Paris, shuts hundreds of schools in Ireland, and disrupts Norway’s bus service in Oslo.

**25** A winter storm hits the Northeastern United States.
Table 7: This table presents dates where the spot price shows abrupt spikes not reflected in futures prices or dates with substantial discrepancies between spot and futures prices. Column 2 shows the spot closing prices, while Columns 3-7 display futures prices. Column 8 shows the footnote reference for those days (or periods) with an unusual or remarkable event.

Appendix of proofs

Our model specification assumes that commodities’ prices are determined by the evolution of two stochastic processes. Under the risk-neutral measure, the dynamics of these processes are given as,

\[ dY_t = \kappa (\alpha + \hat{z}(t) + \eta_t - Y_t) \, dt + \sigma_Y d\tilde{W}^a_t, \]

\[ d\eta_t = -\lambda_\eta \sigma_\eta dt + \sigma_\eta d\tilde{W}^b_t, \]

\[ d\tilde{W}^a_t \cdot d\tilde{W}^b_t = \rho dt \]

where \( Y_t \) follows a mean-reverting process and \( \eta_t \) follows an Arithmetic Brownian motion. Considering the change of variable \( dH_t = d \left( e^{\kappa t} Y_t \right) \) and solving for \( Y_t \) we get that

\[ Y_T = e^{-\kappa(T-t)} Y_t + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda_\eta \sigma_\eta + \eta_t \right) - \lambda_\eta \sigma_\eta \left( T - t e^{-\kappa(T-t)} \right) + \]

\[ \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + i\omega_z} \left( e^{i\omega_z T} - e^{-\kappa(T-t)+i\omega_z t} \right) \right] + \int_t^T \sigma_\eta \left( 1 - e^{-\kappa(T-s)} \right) d\tilde{W}^b_s + \]

\[ \int_t^T e^{-\kappa(T-s)} \sigma_Y d\tilde{W}^a_s \]

Our model assumes that the stochastic process for the commodity spot price at time \( t \), \( S_t \), is given by the sum of two components

\[ \ln \left( S_t \right) = f(t) + Y_t \]

\(^{26}\)David Cameron announces an extra 100 million pounds to deal with the floods that have hit the UK.

\(^{27}\)The English Environmental Agency issues two severe flood warnings where there is a ‘danger to life’ for Somerset in South West England.
Hence, 

\[
\ln (S_T) = f(T) + e^{-\kappa(T-t)} \left( \ln (S_t) - f(t) \right) + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma_\eta + \eta_t \right) - \\
\lambda \eta \sigma_\eta \left( T - te^{-\kappa(T-t)} \right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + im\omega} \left( e^{im\omega z T} - e^{-\kappa(T-t)+im\omega z t} \right) \right] + \\
\int_t^T \sigma_\eta \left( 1 - e^{-\kappa(T-s)} \right) d\tilde{W}_s^b + \int_t^T e^{-\kappa(T-s)} \sigma_\eta d\tilde{W}_s^a
\]

Clearly, the logarithm of spot prices follows a Gaussian distribution under the risk-neutral probability measure \( \tilde{P} \). Applying the isometry property for stochastic integrals in the variance, the conditional mean and variance are given as,

\[
\tilde{E} [\ln (S_T) | \mathcal{F}_t] = f(T) + e^{-\kappa(T-t)} \left( \ln (S_t) - f(t) \right) + \left( 1 - e^{-\kappa(T-t)} \right) \left( \alpha + \left( \frac{1}{\kappa} + t \right) \lambda \eta \sigma_\eta + \eta_t \right) - \\
\lambda \eta \sigma_\eta \left( T - te^{-\kappa(T-t)} \right) + \sum_{n=1}^{\infty} \text{Re} \left[ \frac{\kappa B_n}{\kappa + im\omega} \left( e^{im\omega z T} - e^{-\kappa(T-t)+im\omega z t} \right) \right]
\]

\[
\tilde{V} [\ln (S_T) | \mathcal{F}_t] = \sum_T^2 = \sigma_\eta^2 \left[ (T-t) - \frac{2}{\kappa} \left( 1 - e^{-\kappa(T-t)} \right) + \frac{1}{2\kappa} \left( 1 - e^{-2\kappa(T-t)} \right) \right] + \\
\frac{\sigma_Y^2}{2\kappa} \left( 1 - e^{-2\kappa(T-t)} \right) + \frac{2\sigma_Y \sigma_\eta \rho}{\kappa} \left[ \left( 1 - e^{-\kappa(T-t)} \right) - \frac{1}{2} \left( 1 - e^{-2\kappa(T-t)} \right) \right]
\]
